TABLE OF CONTENTS	3
Preface	13
THE PORTO CHARTER	15
URBAN MORPHOLOGICAL METHODS AND TECHNIQUES	17
Urban morphological elements studies: for describing generated urban form <i>Li Q, Ding W</i>	18
Urban morphology of streets in central area of Vitoria (ES) <i>Botechia F, Thompson A</i>	36
Studies and hypothesis on Mdina and Rabat urban form <i>Camporeale A</i>	47
Territory and urban planning in northern Sinaloa <i>Cataldi G, Urios D, Colomer J, Portalés A</i>	53
The memory of informality: the typological cycles in the self-built environment <i>Montejano M</i>	63
The positive dissemination: interpreting a new process for urban form analysis <i>Gonçalves A, Tomé A, Medeiros V</i>	74
The sociability of the street interface - revisiting West Village, Manhattan <i>Palaologou G, Vaughan L</i>	88
The 'Projeto Orla' (Lake Paranoá, Brasília/Brazil): the creation of an exclusionary lake shore <i>Lembi M, Medeiros V</i>	103
Mapping urban space based on visual perception <i>Zhuang Y, Ding W</i>	114
Changing form of the Baltic cities: resurrection of the suburbs <i>Cirtautas M</i>	121
Mind the gap. Multi-scale landscape approaches <i>Marras F</i>	134
Conurbation in the Porto Alegre metropolitan region <i>Rigatti D</i>	142
Configuration of urban grid and the relationship between apartment buildings location <i>Corrêa A</i>	155
Typological atlases of block and block-face <i>Vialard A</i>	166
Analysis and modeling of spatial changes <i>Weiss R, Santiago A</i>	181
The urban form of the inner port area in Kesennuma, Miyagi prefecture, as source of resilience <i>Abe T, Satoh S</i>	195
Air oriented urban form: to develop an Eco-City in the tropical urban area <i>Mamun M, Begum A</i>	205
Territorial and urban form regulation: from Garden-City to Low Carbon City <i>Mourão J</i>	218
Analysis of tools and 'patterns' for assessment of urban sustainability to promote design quality <i>Otto E, Andrade L, Lemos N</i>	227

Hybrid cellular automaton – agent-based model of informal peripheral development in Latin America cities <i>Santos A, Polidori M, Peres O, Saraiva M</i>	239
Urban street tree modelling using high polygon 3D models with photometric daylight systems <i>White M, Langenheim N</i>	256
The recomposition of urban public spaces. Case study of the historic centre of Noale, Italy <i>Pietrogrande E, Caneva A</i>	268
Landscape design method toward tops of surrounding mountains tops yama-ate in Murakami castle town <i>Sugano K, Satoh S</i>	281
Measuring urban canyons with real-time light based sky view factor modelling <i>White M</i>	293
An approach on describing the street skyline <i>Yang H</i>	305
Urban form and accessibility to rail transit stations: a case study of Auckland <i>Adli S</i>	317
Systems thinking for new perspectives on urban form <i>Stevens N, Salmon P, Taylor N</i>	327
THE EVOLUTION OF URBAN FORM	343
Polish city from conzenian perspective – fringe belt phenomenon in Toruń <i>Deptula M</i>	344
Urban evolution analysis as a means to confirm an outstanding example of a traditional human settlement in Rabat <i>Safe S, Costa S</i>	353
Transformation of the fringe belt units at the perimeter of Avenida do Contorno/Belo Horizonte/MG <i>Simão K, Costa S</i>	370
Urban morphology and architectural design in small towns. The case study of San Vito Romano <i>Ciotoli P</i>	385
Railway as a vehicle of urban transformation. Past and present of the train station <i>Čechová K</i>	388
The impact of Lisbon's subway development on Avenida da República <i>Sampayo M, Silvestre C</i>	401
Urban chronicles: exploring the evolution of the entrepreneurial disposition of Coimbra periphery <i>Tavares A</i>	415
Spatial fabric of urban cemeteries. Two cases in Lisbon <i>Bazaraite E, Heitor T, Medeiros V</i>	427
U+D urban form and design. A tool of urban syntax to design <i>Carlotti P</i>	440
The evolution of house forms and the change of culture: a Turkish perspective <i>Gokce D, Chen F</i>	444
Athens and military architecture <i>Zaroulas S</i>	458
Transformation of urban blocks and property relations: cases from the Historical Peninsula <i>Küçük E, Kubat A</i>	466

The transformation of the urban block in the European City <i>Oikonomou M</i>	484
Morphology and structure of road crossings of the modernist urban ring of Viana do Castelo in the city's general plan <i>Lopes J, Gulas M, Cavaleiro R</i>	498
Urbanization in the Brazilian hinterland's 'forgotten century': growth patterns in Planaltina <i>Palazzo P</i>	504
Hermann Jansen's Grünstreifen in Ankara and their transformation <i>Burat S</i>	516
Morphological process as an instrument for knowing chronological character: a case study in Tainan <i>Chen C, Lin W</i>	528
The evolution of urban form since post-war period in Taiwan – a case study of Yonghe city <i>Chen C, Tsai C</i>	541
Analysis of the correlated relations between ancient Chinese urban morphology and social culture <i>Dai J, Wang Z</i>	551
Morphological evolution of urban form components in the historical peninsula of Istanbul <i>Kubat A, Kürkcüoğlu E</i>	563
A code for the Islamic cities of the Gulf <i>Petruccioli A</i>	576
From 'a miserable town of 150 mud houses' to 'the city that never sleeps' <i>Geddes I</i>	583
Analyzing the effects of hot and arid climate on the form of historic cities of Iran <i>Daneshpour S, Nedoushan M</i>	597
Island-City / City-Island: Island precincts and evolving urban morphology of Abu Dhabi, UAE <i>Mishra A</i>	607
Restelo neighbourhood: a paradigmatic example of urban form overlapping <i>Almeida P</i>	617
Utopia and reality: from Étienne de Gröer to the late 20th century. Évora, Portugal <i>Monteiro M, Tereno M, Tomé M</i>	625
Campo Alegre: the evolution and persistence of a territorial intent <i>Ramos S</i>	635
Is there a transversal organic pattern? Favela and its diachronic relations <i>Loureiro V, Medeiros V</i>	645
The 'Ilhas' of Porto and the 'self-improvement' urbanism <i>Sena N, Doevendans K, Rousseau S</i>	659
The 'ilhas' of Oporto, a fundamental component of the city's nineteenth century urban morphology <i>Teixeira M</i>	674
AGENTS OF CHANGE	685
Influences of housing municipal policy in slum urban form: the case of Heliopolis (Sao Paulo, Brazil) <i>Antonucci D, Filocomo G</i>	687
The auto representative image as an agent of legitimation and incorporation of urban settlements in the city of Rio de Janeiro <i>Hollanda C</i>	697

The origins and pathways of urban (in)formality <i>Rocha M</i>	703
Fernando Távora and the Portuguese urban space design <i>Ferreira C</i>	733
Fourth dimensions urban morphology. Urban geographies of work as a new perspective of urbanity <i>Screpanti D, Carlesi P</i>	747
Change, utopia and ‘the public’: urban transformations and agents of survival in Brasília and Rio de Janeiro <i>Carvalho T</i>	754
Public involvement transformation for best future of cities in Russia <i>Zakharova M, Gudz T, Meltsova E</i>	766
Unidade Residencial da Reboleira Sul <i>Ferreira B</i>	773
Tenure of urban land: structure, form and transformation of the original urban space of the city of Ribeirão Preto - Sp, Brazil <i>Junior D, Salgado I</i>	788
An introduction to the research on use pattern of Lushan National Park based on its cultural landscape process <i>Xiong X, Liu M, Song F</i>	798
From urban sprawl to a compact city policy: the primacy of process over form <i>Cavaco C</i>	810
Interpret planning gap caused from accomplished roads by identifying building forms <i>Chen C, Liang C</i>	822
Events-driven morphological process: a case study of Auckland's Waterfront <i>Shephard T, Gibson L</i>	833
Assessing the effects of governing thoughts on the form of cities <i>Daneshpour A, Soleimani A, Charbgoo N, Ashnaee T</i>	848
The evolution of neighborhood model as a manifestation of political regime shift <i>Ghonimi I</i>	866
Power, ideology and space re-generation: Istanbul case <i>Özden P</i>	887
Within and outside virtual walls <i>Braga A, Trusiani E, Rigatti D, Ugalde C, Zampieri F, Reckziegel D</i>	902
Analysis of urban morphology on festival space decorated on urban space, focusing reviewing spaces and closed spaces in the case of Chichibu Night Festival in Japan <i>Matsuura K</i>	918
Mi casa es tu casa <i>Scarnato A</i>	921
The role of municipality in urban regeneration: the case of Lisbon's Eastern waterfront <i>Nevado A</i>	932
The re-appropriation of industrial sites in the urban form of the post-communist city <i>Statica I</i>	940
Urban mobility - Urban mutations. Means transport and morphological changes in the city of Belém <i>Andrade F, Silveira I</i>	948
Tracing urban catalysts in ‘Noorderkwartier’ area <i>Waijjer A</i>	955

Managing the mark of the memory <i>Moreira M</i>	967
New University Complexes as a force of shaping the urban form of the medium sized cities in contemporary Iran, a case study of Najaf Abad <i>Nasserian A, Klets V, Kalbasi S</i>	985
Urban black holes: the rural in the urban as liminal spaces from where to build a new city <i>Santos P, Pena-Corvillon D</i>	995
Exploring university morphology. Bergamo as case study <i>Silva L, Heitor T</i>	1001
Aging as an agent of change in the way how we occupy our territory <i>Bordalo A, Matos M</i>	1011
FIFA Confederations Cup Brazil 2013 and urban conflicts in Belo Horizonte, Minas Gerais, Brazil <i>Gonçalves R, Simão K, Araújo J, Pedroso A</i>	1025
Urban morphologies of alternative spaces: a case study of Tehran <i>Soleimani B, Staub A</i>	1036
REVISITING URBAN MORPHOLOGICAL CLASSICS	1047
Comparative notes on Saverio Muratori and Ludovico Quaroni's urban projects <i>Del Monaco A</i>	1048
Re-thinking city. An exemple of Ilse's multidisciplinary approach to urban morphology questions <i>Nicosia C</i>	1060
The influence of classics on contemporary thinking Louis Kahn and Hestnes Ferreira <i>Saraiva A</i>	1068
MULTIDISCIPLINARITY IN URBAN MORPHOLOGY	1091
The study of urban form versus water management: lessons to a sustainable urban future <i>Marat-Mendes T, Mourão J, Almeida P</i>	1092
Morphology and functioning of the metropolitan urban areas <i>Benaïche A</i>	1107
The city, the river and mangroves: a case study in San José, Santa Catarina, Brazil <i>Monteiro E, Weiss R, Barea G</i>	1122
Urban growth and hydrography: convergences on landscape morphology <i>Peres O, Polidori M, Saraiva M, Santos A</i>	1135
Epistemology of public spaces: a cultural approach <i>Hanzl M</i>	1151
The interaction between urban form and public art. Two examples on Lisbon's waterfront <i>Ochoa R</i>	1160
The impact of urban form on wind energy potential <i>Wang B, Cot L, Adolphe L, Geoffroy S, Morchain J</i>	1166
Heritage, infrastructure, structure and urban form <i>Nascimento A, Silva M</i>	1176
Morphological structure and system community facilities <i>Schäfer K, Oliveira L</i>	1181
Housing development transformations: political directives and post-occupation life <i>Teixeira M, Maciel M, Alonso P</i>	1192

Unsustainable empty by inadequate use of urban space <i>Carvalho M</i>	1202
Interactions between agricultural-systems and urban forms in Sardinian villages <i>Dessi A</i>	1215
Study on the sustainable development of urban fringe at the background of urban and rural co-ordination in China <i>Ying W</i>	1227
Contributions to the study of urban morphology <i>Dias F, Campos M</i>	1238
A construction perspective of urban morphology study in Shanghai Alleyway House <i>Ni J, Liu G</i>	1257
The effects of urban form on levels of integration of housing schemes and social interaction among residents <i>Lay M, Lima M</i>	1269
Characterization of the relationship between commercial plots and building patterns <i>Jiang J</i>	1281
Municipal average building capacity <i>Rebelo E</i>	1293
The morphological sense of commerce <i>Saraiva M, Pinho P</i>	1307
The systemic focus on walkability and urban form <i>Barros A</i>	1322
By São Paulo sidewalks: urban form and walkability <i>Degreas H, Katakura P, Santos C</i>	1331
The elements of urban morphology which influence residents' leisure walking activities <i>Mao J, Chen Y</i>	1338
COMPARATIVE STUDIES OF URBAN FORM	1349
Urban transformation in meeting places: the cases of Bursa & Yazd <i>Eslami S, Kubat A</i>	1350
Environmental evaluation method of urban spaces <i>Teixeira E, Romero M, Cantuaria G</i>	1364
Comparing urban rules for urbanizing villages in Hong Kong, Macau and Shenzhen <i>Tieben H, Chu J, Soares N, Chungyim E</i>	1374
A study of urban space form in areas with different economic development level <i>Xiong G, Cao B</i>	1389
Gilberto Freyre's work: between urban morphology and building typology – first approaches <i>Aragão S, Marques A</i>	1399
Meeting of minds: investigation on the common concepts and different approaches of the major schools of urban morphology <i>Costa S, Netto M, Moraes L</i>	1409
Urban analysis techniques and role of morphology in post crisis urban design <i>Delsante I, Bertolino N</i>	1413
Past and present: an architectural survey of Birnin Lafiya, a Dendi village <i>Pinet J</i>	1422

Urban form and its implication for the use of urban spaces 1433

Isfahan School of urban design: a morphological perspective <i>Arefian F, Estaji H, Jabbari M, Koledova A, Fatemi M</i>	1795
Discussion about the similarity of the forms of the cities of Porto (Portugal) and Qazvin (Iran) <i>Jabbari M, Ramos R</i>	1808
OPEN SPACES AND THE NEW BRAZILIAN URBAN FORM	1817
Open space systems and the constitution of the contemporary Brazilian urban form <i>Queiroga E, Macedo S</i>	1817
Open spaces and urban form: a systemic relation <i>Campos A, Queiroga E, Custódio V</i>	1827
Landscape units as territorial analysis procedure <i>Montezuma R, Tangari V, Isidoro I, Magalhães A</i>	1838

The landscape of sprawl: relationships between natural and urban dynamics in the Western Portion of the Metropolitan Area of São Paulo <i>Coelho L, Macedo S</i>	1849
Integrated approaches in Vitória workshop: a study on open space system and the urban form in Brazil <i>Mendonça E</i>	1863
BRAZILIAN MORPHOLOGY	1885
The urban form of the housing policy <i>Minha Casa Minha Vida</i> in the metropolitan area of São Paulo <i>Donoso V, Queiroga E</i>	1873
Open spaces system: describing the urban morphology of Vila Mariana's district <i>Degreas H, Macedo S</i>	1885
Urban form and multidisciplinary: contributions to the São Paulo Master Plan revision <i>Queiroga E, Meyer J, Macedo S</i>	1896
Public policies towards river and streams restoration: perception and appropriation <i>Galender F, Campos A</i>	1905
Morphologic transformations of public spaces in the surroundings of Nova Lima's churches <i>Maciel M, Teixeira M</i>	1918

Preface

This year the International Seminar on Urban Form (ISUF) celebrates its twentieth birthday. Over the last two decades, the ISUF annual conferences and the journal *Urban Morphology* have steadily established as the main references of morphological debate worldwide.

The development of ISUF included the formation of affiliated networks. The Portuguese Network of Urban Morphology (PNUM) was established in 2010 at the Hamburg conference. In June 2011 the PNUM launched its annual conference and in December 2013 it published the first issue of the *Revista de Morfologia Urbana*. Against this dynamic background, and for the first time in two decades of history, the ISUF annual conference takes place in Portugal.

‘Our common future in urban morphology’ has a record number of presentations. Almost 400 presentations are included in the conference programme comprising four plenary sessions and 80 parallel sessions. This book, composed of two volumes, follows the structure of the conference. Volume 1 gathers the abstracts of all communications included in the conference programme. Volume 2 includes the full papers submitted to the conference.

The plenary sessions of ISUF2014 include an overview of the urban form and structure of Porto; a debate on different approaches in the study of urban form (the German morphogenetic approach, the Conzenian school, the Muratorian school and space syntax); the description of a repository of urban tissue; and, finally, the presentation of recent work developed by the ‘ISUF Task Force on Research and Practice in Urban Morphology’, particularly of four case studies of application of morphological concepts and methods in professional practice and of the ‘Porto Charter’ including ISUF’s fundamental principles.

The 80 parallel sessions are structured around ten fundamental themes (including also five special sessions): urban morphological theory; urban morphological methods and techniques; the evolution of urban form, agents of change; revisiting urban morphological classics; teaching urban form; comparative studies of urban form; multidisciplinary in urban morphology; integrated approaches; and, finally, the relations between research and practice. The debate of these themes should help us to understand what should be our main contribution as urban morphologists, how it could be part of wider integrated research on cities, and how this could be applied into day-to-day practice.

Paulo Pinho

The Porto Charter

ISUF seeks:

To promote urban morphology as the study of the physical form of cities.

- a. To demonstrate the relevance of urban morphology at all scales, from the individual building to the metropolitan region.
- b. To facilitate the international dissemination of urban morphological knowledge, techniques and experience.
- c. To promote recognition of the cultural and environmental significance of urban form and the importance of its contribution to social and economic well-being.
- d. To stimulate the interaction of intellectual enquiry and practical activity in endeavours concerned with urban form.
- e. To facilitate communication across the range of professions, disciplines, intellectual traditions, and communities of interest concerned with urban form.
- f. To foster comparative studies and assess the impacts of the transfer of concepts and experience in different environments and societies.
- g. To promote and facilitate the study of urban form in the training of built environment professionals.

Urban Morphological Methods and Techniques

The identity of any field of study or discipline is inextricably bound up not only with what the discipline does but the way it does it. We are defined, in part, by our methods not least because methods to a large extent fall out as a logical consequence of the subject matter. At the same time, our methods are a reflection of where we want to go with the subject and what we want it to become. But what happens when the field is multi-disciplinary and the subject as multi-faceted as the city? What happens when 'we' are architects, archaeologists, anthropologists, geographers and historians? The multiplicity of methods potentially becomes a liability rather than an asset. The step back out of this corner is the recognition that urban morphology is, in part, a meta-discipline, a fact that goes back to the inception of the field. Goethe in his preliminary notes on morphology set out the following sequence of thoughts. "Characterization and limitation of the field in which we are working; i) phenomenon of organic structure; ii) phenomenon of the simplest structure which appears to be a mere aggregation of parts but often explainable just as well through evolution and epigenesis; iii) necessity of considering all expository methods together, not to thoroughly explore a thing and its nature, but to give at least some description of the phenomenon, and to impart to others what has been perceived and seen (Goethe 1952, p85). The last note provides the perspective that gets us out of the corner. The multiplicity of methods becomes an asset when we see that one of the roles of morphology is to coordinate the findings of other disciplines around the unifying aspect of *form* (Wilkinson 1962). This is not to say we don't have 'in-house' methods, far from it. It is to say that the coordinating framework is part of morphological method. So, whether the primary investigation is in-house or not, part of what we need to do is to *situate* the results within the framework. To make the most of the information we need to see where it sits within to the body of accumulating knowledge and how it is related to the other parts.

Karl Kropf

Urban morphological elements studies: for describing generated urban form

Qian Li, Wowo Ding

School of Architecture and Urban Planning, Nanjing University

E-mail: liqian82@nju.edu.cn, dww@nju.edu.cn

Abstract. *Urban morphology represents entire city areas or built environment consisting of two parts: generated form and planned form, in terms of their growing processes and morphological characteristics. In classic urban morphological theories three morphological elements, such as streets/blocks, plots and buildings have perfectly defined urban physical form. However, these elements are constituted as the top-down hierarchical mechanisms, which could not fully express morphological feature of generated form. Following previous morphological studies, it is worthwhile to further examine these uncertain conditions. To clarify the relevance of morphological elements and characteristics of two forms, four cases including both generated form and planned form were chosen from the same area: southern Jiangsu province. Based on morphological analysis a comparative study was made among those cases. This paper will present that typo-morphological studies could differentiate varieties of morphological elements and define their correlations with the type of tissues. The results could be transformed as design methods in urban design practice.*

Key Words: Settlement pattern, typo-morphology, morphological element, generating process

Introduction

Recently, the big challenge in front of architects and urban designers is how to deal with the problem of the built environment, which leads to urban studies gained popularity among architects and urban designers in recent years, dealing with land use, place making, site analysis and descriptions of physical feature. Since urban design practice has to consider various factors such as developers' requirements, city governors and public users, so that studies have to be done from different aspects and angles, six dimensions were shown by Carmona and Tiesdell (2007). A plenty literature made for constituting urban theories through years, the value of urban design has been demonstrated, however, what is the core of urban design theories remains unclear. Cuthbert argued 'that mainstream urban design in fact collapsed around its own limitations and it now in need of a paradigm shift towards a deeper theoretical engagement with the world' (Cuthbert 2007); while Marshall proposed that 'urban design to take a freshly critical look at itself from a scientific perspective', which 'is the need not just for 'more and better science', but more specifically, more systematic verification and critical assimilation of scientific knowledge within urban design theory' (Marshall 2012). Taking these views, urban study has been held to correspond to the knowledge of generating urban form and thus to be susceptible to description by urban morphology.

On the other hand, more urban studies from urban morphologists, their works focus on the tangible results of social and economic forces and analyze urban evolution its formative years to its subsequent transformations, identifying and dissecting its various components (Moudon, 1997). The work of Conzen, Caniggia and Kropf has been particularly relevant, that knowledge system of urban form is being constructed by normative scientific researches by involving a reduced set of physical elements to describe and explain the city in morphological terms: the streets, the plots and the buildings. Joined by geographers, architects, planners and sociologists, Urban Morphology constitutes an interdisciplinary platform, which is more appropriate for variety disciplines with a broad discourse (Ley, 2012). Recently, one of the most significant topics based upon urban morphological platform is trying to bridge the gap between urban

morphology and urban design or planning practices, that will help to make up the lack of urban design theories.

As tangible form, two specific terms are particularly important for urban design, which are urban tissue (Moudon, 1996) and typomorphology (Moudon, 1994, Kropf, 1996, 2006, Samuels, 2008). In Caniggia's term the urban tissue is a structure of element or association of buildings, which has been further developed by Kropf proposed three useful conceptual tools: the outline, the desired spatial scale and the degree of particularity used (Hall, 1997). As a physical entity, urban tissue is not only identifiable object for urban morphological research, but also understood as objects by urban design. Typo-morphological studies have been used as a design tool throughout architectural history, the work done by Krier brothers and Aldo Rossi shows quite fruitful, particularly in the sense of type of urban fabric, buildings and open spaces, as well as with socioeconomic processes. Typo-morphological studies use building types to describe the physical form of cities and the process of accumulating of human habitats, which is useful in understanding the three dimensional structure of the city and its underlying formation process. As Moudon (1994: 290) states, "typo-morphology offers a working definition of space and building type, and serves as a rich launching ground for studying the nature of building design, its relationship to the city, and to the society in which it takes place. Therefore, typo-morphological studies are not only good for analysis of existing cities, but also build the theoretical base for urban design practice, since it has influenced certain strands of thought in urban planning and design through urban geography and urban morphology during the European urban development (Carmona et al., 2006: 219).

The most typomorphological studies have done within the circle of morphologist seldom appearing in urban designer. Marshall (2011) have set very clear division between urban morphology and design: "separate hemispheres of the brain", he suggested that urban morphological analysis should be tailored more towards the kinds of abstraction that are most useful for designers to use in practice, from designer's view such abstraction is "Type". In design field, normally typology can be seen as methodology guiding problem solving, since each type is tied closely to a class of problems in the reality, thereby, if connecting typomorphology to urban design practice or forming urban design theory, it has to have attribute of designing not only research. Therefore, this paper tried to follow the term of urban tissue and typomorphology and analyze them systematically from urban design perspective.

Four cases are selected in the same area, in order to have the same properties in land features, geomorphology, economic conditions and cultural features, but different in urban morphological structures. The purpose of selection is to focus on analyzing the relation between morphological elements (building-parcel-block-district-territory) and typomorphology. Base upon examining morphological elements this article try to answer what are different between those types? Why they are different, the forming process is interested for designer.

Settlement pattern and morphological elements

Tangshu, Jin, Jincunyu and Huyuan are four residential communities in Southern Jiangsu Province (Figure 1) which cluster farmers. They belong to one of China's best farming areas, which has a sunny, warm and humid climate. The blessed water resources offer convenient conditions for agriculture irrigation and transportation. Jin has existed for over 1700 years, with many ponds crisscrossing, while the more than 1500-year-old Tangshu maintains a traditional structure of centralized farmlands surrounding by ponds. In terms of sites for houses, the farmers follow the settlements' characteristics of being intimate with rivers, building houses along the rivers, and keeping the houses facing south. Their courtyards are mostly embellished by green lands for good ventilation and sunshine, convenient water resource and pleasant scenery. Different from the traditional layout of villages, Jincunyu and Huyuan have a pattern

similar to the urban areas, with convenient communications. They have been newly-established in recent years due to market causes.

Figure 1. Four selected cases are located in southern Jiangsu Province in China (source: Google Earth).

The four communities have similar conditions of the waterside settlements and they adopt production modes equally emphasizing agriculture and sidelines, with hardly any families not farming. Jin operates handicraft as its sideline, while Tangshu engages in fishing due to its geographical features. Although Jincunyuan and Huyan are separated from the old villages, their residents still keep the occupation of farming. Most of them travel back and forth between their cultivated lands and dwelling places every day. Tangshu, Jin and Huyan have similar sizes between 10-12 hectares (respectively containing 181, 201 and 242 families), while Jincunyuan is a little larger than the former three, about 15 hectares (containing 366 families). According to the local policies, every family shall be allocated the curtilage (including the house and the vacant land in front of or at the back of the house) based on the per capita cultivated area. With the accelerating urbanization in recent years, township industry has emerged and developed quickly, which is gradually changing the farmers' employment structure. The traditional settlements are starting to be removed and merged into new farmers' communities like Jincunyuan and Huyan. Some residents are replacing the original curtilages with houses in the new communities. However, the policies and standards for curtilage approval remain unchanged.

The same region and living habits, similar scales, production modes as well as specific history and regulations generate different settlement patterns: grid pattern or cluster pattern. In the following text, we will analyze and compare the four cases from a designer's point of view with indicator, plan issue and spatial characteristics, and explore and interpret the relationship between the morphological elements and typomorphology.

Planning indicator

This section intends to identify the relationships between different settlement patterns and morphological standards (density, height and floor area ratio). The denotations of the indicators are directly influenced by the calculated areas as the two traditional communities have a loose planar structure while the new ones are compact. It should be noted that the traditional communities are defined by unclear boundaries, depending on the natural conditions such as the curb stones, borders of the green lands and water revetments. Therefore, the indicator calculated accordingly is just a general concept which indicates the relationships between buildings or between a building and other open spaces (including roads, green lands, squares and water

bodies). However, equal to the urban plots, the morphology standard for the curtilages in the selected cases can better define the figure-ground relationship of such specific private sectors. As a result, the sum of the curtilage plots is regarded as an indicator different from the dwelling area.

Plot density

The plot density is only discussed in terms of the dwelling area. In the traditional settlement pattern, the cultivated lands interweave with the village dwellings and consequentially enlarge the village. However, the new farmer communities are essentially same as the urban communities, excluding the agricultural lands and only supporting the dwelling function. Therefore, the coverage rate of the curtilage plots is noticeably increased.

Floor Space Index(FSI)

The plot density only shows that the mode of land use varies with the settlement pattern. The floor area ratio linking up with the building volume seems more relevant to fabric form of the settlement pattern. In terms of the dwelling area, the new communities have floor area ratio are nearly twice as large as those of the traditional communities. However, the equal floor area ratios do not generate the same form. Although Tangshu and Jin have the equal floor area ratios of 0.36, their form characteristics are still different.

Coverage Space Index (CSI)

"The acknowledgement of a city is related to a certain building density and a sufficient construction area," (Salat,2011) same as the dwelling community. In terms of the plot indicators, the curtilage approval measures regulate that, the housing area shall not exceed 70% of the curtilage area. The new communities comply with the regulation on building density while keeping the value above 60%. However, the traditional communities have building densities only about 50%, generating a figure-ground relationship of 1:1 with the vacant land in front of or at the back of the house.

Building height (L)

The relationship between the building height and the street width influence the spatial form of the dwelling area(Figure3). Almost all buildings in the new communities are two-story and even three-story, with an average height not less than 2. Although most of the farmhouses in the traditional communities have transformed from tile roofed houses to buildings, there are still many one-story houses, pulling down the average building height to around 1.6.

Open space ratio (OSR)

Intrinsic relationship between the interweaving private sector and open space on the curtilage compose the spatial characteristic elements of the farmers' settlement pattern. The new communities have a single nature of land use and greatly reduced open space, only half of that of the traditional communities. Tangshu and Jin contain dwelling plots and cultivated lands, green lands and ponds besides, making full use of lands of all natures and enlarging the open spaces.

Results

With Meta Berghauser Pont and Per Haupt's method(Pont, Haupt, 2005), summarize the four indicators (FSI, CSI, L, OCR) that more directly influence the forms of the selected cases(Figure4). The morphological standards vary with the settlement patterns. The planning indicators of new and traditional communities respectively occupy an area in the coordinate system, which explains the communities' morphological difference in a certain extent. However, the planning indicators cannot determine the forms of the patterns, and the settlements in one group with the similar indicators display some different characteristics (to be discussed in detail in the next section). In addition, the construction phases, architectural modes and spatial arrangement can influence the generation of a unique and distinctive morphological system, but the indicators cannot.

Characteristics of plot and building

Starting from the cases' basic forms and in terms of plan issue and spatial characteristic, this section will, based on the patterns' status quo, outline their morphological characteristics, tease out their morphological elements and identify the differences between the morphological types by comparing and analyzing the elements, so that some elements could be gained for typomorphology design.

Subdivision of plots

Overall planning for Jincunyun and Huyan is initially divided into plots by roads, and then the plots are subdivided to curtilages with equal areas. Each curtilage has a side-way in front of and

at the back of it, and all curtilage have their own concession roads of the equal length. In the old Tangshu and Jin, the division of most of the plots has no relationship with the road system, because the curtilages are approved only based on quantitative indicators and the farmers could select the position at will. Additionally, the houses are not built in the same time, and some plots has no relationship with surrounding curtilages; therefore, the communities' layouts are relatively disorderly. (Figure 5, Table 1)

Plots and buildings

In the selected cases, most of the curtilages have houses in the north and yards in the south, which ensures the houses keep a certain distance from neighbors on the south side and get good ventilation and sunshine. Otherwise, Tangshu and Jin create diverse relationships between plots and buildings. The houses and side-located auxiliary room enclosing the yard to form an "L" shape can commonly be found. (Figure 6, Table 2)

Arrangement of buildings

The traditional communities seldom juxtaposed over three buildings. If needed, the buildings would be staggered or keep a certain distance from each other for passing through. The new communities are prone to follow the building code and save the cost of excessive road, thus the buildings are arranged as the military camp, with over 4 buildings in a row, even up to 10, except those in some corners. (Figure 7, Table 3)

Distance of buildings

Analysis on the sample of the pattern profile shows that the traditional communities are almost entirely for dwelling, and have fewer public open spaces because major public events are held in cities or towns. The families are of similar demographic structures and economic conditions, so that there are few differences in the boundary and volume of the house. The distances between the buildings usually are suitable and unfixed, depending on the vacant lands and green lands between the curtilages. The new communities no longer consider the feasibility for farming. As a result, the distances are uniform, with an average value slightly higher than that of the traditional communities. (Figure 8)

Road crossing

The amplitude of space change is directly reflected by the diversity of the road crossings in the community. Twists and dislocation of the road crossings diversify the landscape. The new communities have much more road crossings; however, the forms of the road crossings are less diverse. Almost all of them are orthogonal. (Figure 9, 10, 11)

Street space

In traditional communities, the houses are built along the rivers and orientated according to the river direction. Then lanes generated between the buildings. Both the house orientation and courtyard wall direction are generally not parallel with the streets and lanes, and accordingly create the unique spatial characteristics. Without designing the building orientation based on the river direction, the centralized-built new communities lose the spatial and morphological characteristics of the traditional ones. (Figure 12)

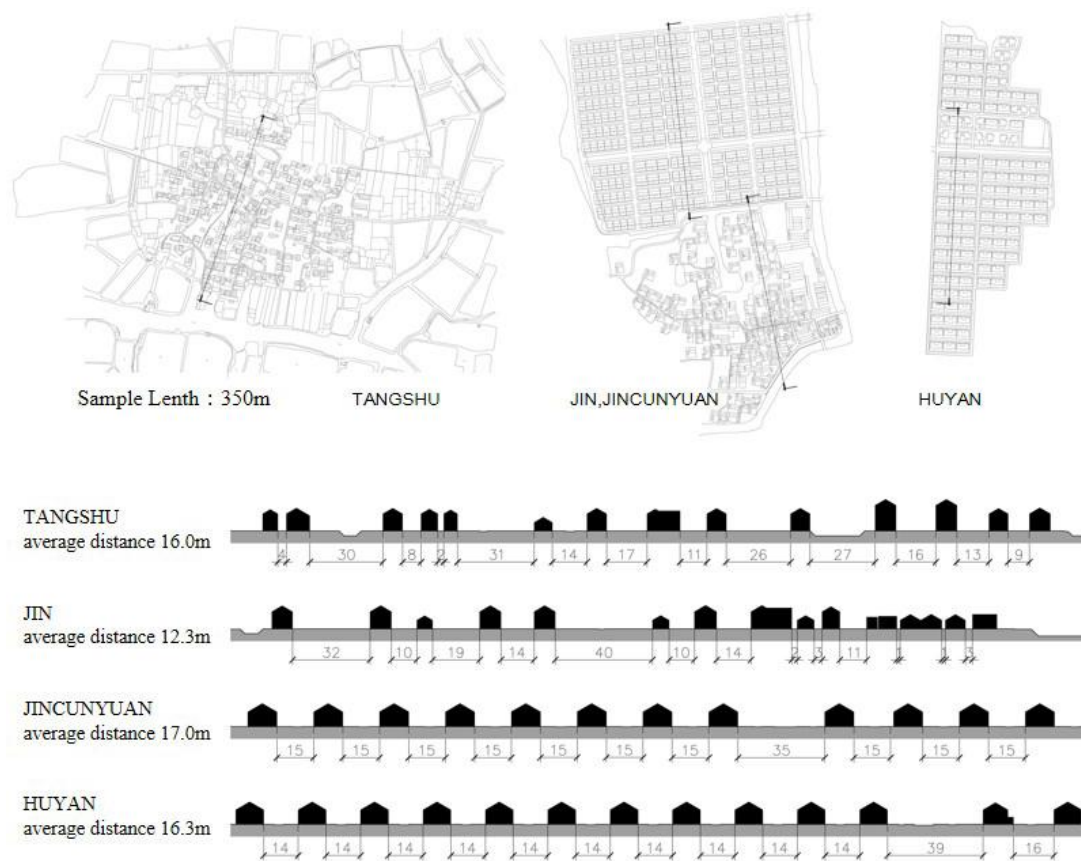

Figure 8. Distance of buildings (sample length: 350m, direction: north-south), based on authors' field survey.

Plan of buildings

In terms of layout design, all the four communities follow the farmers' habits and customs, with the central room connecting all other functional rooms, but the new communities are additionally deployed with a garage for each family, closer too villas in cities. However, the two types of communities also have a difference. In Tangshu and Jin, the neighboring courtyards are generally directly connected or connected through the side-way at the east and west sides. In

new communities, the two buildings are completely separated, and can only access to each other through the main road. (Figure 13)

Building forms

Traditional communities have a morphological characteristic that a row of houses have different layout as the unit plan is affected by the era when the houses built. However, the new communities planned and built in a unified manner have uniform geometrical form. Additional, a house's era can tell us the development trend of its materials and style. However, even the houses built at the same time employed inconsistent styles and building methods because these were determined by the owners of the houses. (Figure 14)

Figure 14. Building forms in different ages. A. Plan and section. B. Elevation.

Results

Table 4 reports the results of measurement of the above-mentioned 8 morphological elements. Overall, the new communities are more in line with the level-by-level control on urban morphological elements from the street to building in the urban morphology theory. Traditional communities are gradually formed by gathering houses in which house construction has relations with family development, house situating has relations with the neighborhood, as well as the unit plan has relations with the era when the houses built. Comparing the morphological elements, we can find that the two types of patterns: *grid* and *cluster*, have entirely different control hierarchy on the morphological elements. The following text will analyze the generation process of these two morphological types to find the inherent laws and their morphological units and hierarchy. (Table 4)

Topography and generating process

The main objects of study are established typomorphology and the morphological elements. We considered that the form of the traditional communities were generated based on complex causes, related to natural and social environments. With the historical evolution, its morphological elements are double affected by the nature and human, finally forming a community form interdependent with the natural landscape and holding relatively stable social relationship. This form is generated during a long process of coadaptation and interactivity. In addition to the environmental elements, the awareness and values of the community also contribute to the generation process and element structure of the form.

Topography

The traditional inhabited space of farmers is gradually generated, developed and evolved during the course of human adapting to the environment (including the natural and social environments). Topography here is generalized, which not only includes the characteristics of the landscapes (including the terrain and ground object) in specific plots, but also involves the

built environment existing in the plot before (such as the spatial layout of the existing houses and the social relationships between the residents).

Because the cases give priority to the plain geomorphology of waterside settlement, the community form of water network dominates. The habit of living by rivers make the form of the traditional settlements corresponds with the river form. The river system structure determines the form and structure of the pattern, while the direction of the water revetment determines the house orientation. While building houses along the river, the farmers tend to keep them facing the river, with the orientation parallel or vertical to the river and without forming an included angle with it. Jin's water system consists of rivers and ponds; therefore, the houses turn with the rivers. Tangshu's water system gives priority to small ponds, and the houses are consequently built around the ponds with consistent orientation, although are loosely arranged. (Figure 15)

The water determines the orientation of the house, and the built environmental factors are concerned with selecting dwelling places. They express the relations between the people and the environment. The villagers have a very concrete understanding of environmental space. Only when they are in it, there is a value to consider “at this time and place” (Wang, 1997). Moreover, a traditional village is the outcome of living together, and the result of relations between houses. In our investigation, we found that the combination of houses fully reflect the social relations between people. To build a house close to the neighbour, roughly sharing the environmental space need first to be agreed upon, and then the positional relations with the existing houses are taken into account.

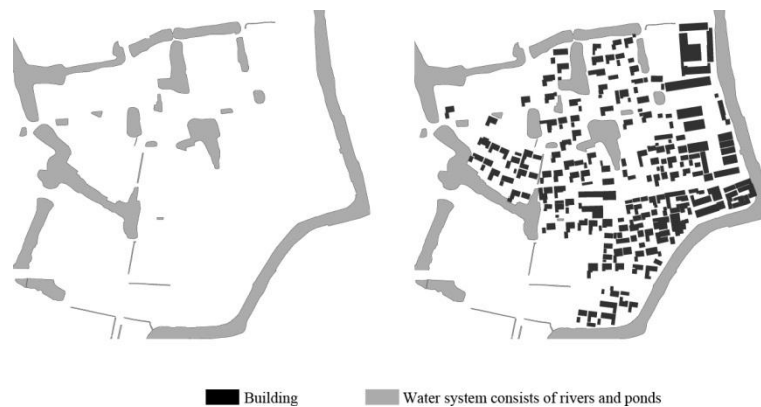

Figure 15. The buildings turn with the rivers and ponds in Jin, based on author's field survey.

Buildings

The location and orientation of the houses are determined by people, but the plan layout and elevation style are closely related to the era. The old houses built before 1949 were mainly 3-bay, with the door on the central room and one more room built on each side of the central room. Between 1949 and 1980, old house renovation dominated due to the production system and economic level, which extended the depth and turned the structure to 5 rooms of 3 bays. In early 1980s, the tile roofed houses were transformed into buildings with the corridors downstairs and balconies upstairs for living condition improvement. From 90s onward, the functional layout started to incline to the urban lifestyle, and some houses were even enlarged to 4 or 5 bays with each son owing a room.

The house style is directly affected by the local culture. The farmers advocate a simple but elegant style (white wall and black tiles) whiling tending to accept innovation. As a result, the facing material transformed from the whitewash to mosaic and face brick, and then to new paint with the main color tone kept as white. The balcony railings appeared and evolved from wooden, cement, granitic plaster to now close type. Simply put, the new materials appear in

cities will be adopted in farmers' new houses two years later. The only unchanged characteristics are the pitched roof and its bratticing.

Plots

Facing to the south is common in farmers' settlements in Jiangsu Province. The vacant place in the south side of the house can be used as a passageway and a place for working or stacking straw or other things.

While building houses, people always pay more attention to the completion of the house, but ignore orderliness of the plot. Policy control over the plot only involving the quantitative indicators also contributes to this result. The private area usually keeps a loose relationship with the surrounding vacant places, and the borders of the vacant lands are uncertain. However, there is an order accepted through common practice. That is, the borders of the plots that face to the houses are nearly parallel to the house, although they are not very orderly.

Streets

During the times of agricultural cultivation, there were roughly two types of streets in the traditional villages: one for external traffic and one for the internal connection of farmhouses. The houses were always built first, then the streets. This process is quite the opposite of the construction of modern residential quarters. Streets are referred to as the structural frame or skeleton in a modern residential quarter, but in a traditional village, streets are just the open spaces between farmhouses for the use of traffic. Therefore, the street system in a natural village was initially not the support of the village; instead, streets were developed in response to the farmhouses.

To sum up, the traditional settlement pattern in rural areas have different morphological elements with those in urban areas. Its morphological hierarchy is that topography determines the house orientation and location (the house type are related to the era of construction), the plot of land of the house determines the private plot, and finally streets are generated between the houses. In contrast, the new communities have a planned settlement pattern. Its generation process is in line with the level-by-level control of streets/blocks-plots-buildings in the urban morphology, which is reverse to that of the traditional communities, topography-buildings-plots-streets. Therefore, the generation mode of morphology is a major factor that influences types of settlement patterns.

Conclusion

Through the analysis of both settlement patterns of grid or cluster in Southern Jiangsu the various factors have taken into account for examining their roles on the generation of the type of the pattern, which include the set of planning indicators, the morphological elements in terms of design aspects and environmental values. The way of such analysis is aiming for searching the factors that could act as designing elements in practice, such as the factors to determine building position in the plot, group of buildings arrangement and building body shaping. The second is testing whether morphological elements for describing could also match to the operational factors acting in the design process.

First of all our study has shown that settlement pattern in terms of urban tissue formed by very complex reasons: planning regulations and site plan indicators, decision making of placement or site plan and environmental value judgments. Through typo-morphological studies tested with both settlement pattern of *grid* or *cluster* clearly proved there is the correlation between the types, morphological elements and formative process, which gives certain evidence for supporting typo-morphology acting as a kind of urban design theory.

Analyses of morphological elements in different views are critical, such as planning control, form describing or building placement. In our case studies that planning indicators and regulations are important for housing settlements, but are not effective factor for forming physical pattern. Morphological elements introduced by Conzen and Caniggia have shown their powerful capabilities in differentiating settlement patterns: grid pattern or cluster pattern. Furthermore, our study has also found that not all the elements or factors are operational in terms urban design. According to our research plot configuration, house placement, street structure and their density, and building interface and street crossing pattern are the key issues for the type of the settlement patterns. Planning indicators and regulations are the simple role for forming grid pattern, while structure of natural elements, such as river, pools and hills are the important reference for the house placement in cluster pattern.

Most morphological studies recognized that urban design takes place in reality at the nexus of the users' requirement, the government's control and the designers' knowledge base, while designer intention is seldom considerate. Design Intention is based on "requirement", "controlling indicator" and "design knowledge (partly contributed by morphological study)", but go beyond of them. Norberg-Schulz proposed a phenomenological method in order to understand and describe the "spirit" of the place through a depiction of its physical features and an interpretation of the human experiences within that place (1980). His theory helped us to understand the meaning of the pattern of cluster, as well as decision making with intention of the place. Research on the relationship between physical features and human perception of the places has to be further studied.

Finally, during our case studies we have found that 'typological process' of Caniggia and the 'plan elements' of Conzen (Levy, 1999) could be understood in different design methodology although they were made equally in morphological terms. As Hall cited (1997) that Caniggia developed his down-top morphological hierarchy and Conzen's concept of plan-unit was other way around. In our cases the settlement with grid pattern could be described by Conzen's top-down hierarchical mechanisms, while the settlement with cluster pattern could suit the theory of Caniggia. This result should be taken account by designers.

Abstract. *It is proposed the construction of a urban form study, from the analysis of streets and its typological variations, of the central area of Vitória (ES), featuring characterizing the relationships between physical elements (buildings, lots and streets) through analysis of floor plan and cross-sectional profiles, produced with graphic scale, in order to allow for correlations between physical elements (buildings, lots and streets) through analysis of floor plan and cross-sectional profiles, produced with graphic scale, in order to allow for correlations between studied elements of different typologies. The theoretical framework is based on Moudon (1994), Borthagaray (2010), Proença (2011), Panerai et al. (2013). The registration and analysis of cycles of urban transformation of the physical dimension of certain tissues, give a meaning to the study of morphology, when combined with the practice of urbanism, the potential to be effective instrument for the design of the city. The central area of the city of Vitória (ES) is chosen as a pretext and context for the development of a study group, with reference in urban morphology, because it is the subject of frequent analysis of the student of architecture and urbanism, holds proximity to the urban reality, has current reliable Cartographic base.*

Key Words: urban morphology, central area, typology, Vitória (ES)

Introduction

This article is part of a research that has been developed, since 2013, in a College of Architecture and Urbanism - Brazil, which main objective is the creation of an academic research environment through the proposed analysis of the urban form in the central area of Vitória (ES), studying specially the streets and its typological variations. This study's group was created by the Professors Msc. Flavia Botechia and Agnes Thompson, had the support of The Institute of Education Multivix –Vitória and for scientific initiation by FAPES-ES¹, and involved the graduation students Joyce Andrade da Silva, Ana Carolina Rosa Marques, Fernanda Careta Ventorim, Giovana Gonçalves Achiamé, Pedro Queiroz França and Valdomiro de Souza Neto.

Presents itself at this point the partial results of the analyzes developed by teachers and students, fellows and volunteers, highlighting the physical categorization of the object of primary interest. This article is structured in two parts. At first, it was intended to bring together a theoretical framework about the street as the scene of events and life (Borthagaray, 2010; Ascher, 2010); as a morphological element (Kohlsdorf, 1996; Moudon, 1997; Lamas, 2000; Panerai, 2007) and as an object of categorization and analysis. The main theoretical reference is the morphological studies of the French School or "Versailles", represented here by Philippe Panerai in his works entitled "*Urban Analysis*" (2007²) and "*Urban Forms*" (2013). Was also important for applied research the example of Proença (2011), "*The diversity of street survey in Lisbon*", which gives further characterization performed by morphological inventory of street in Portuguese cities (Forma Urbis Lab - Faculty of Architecture/Technical University of Lisbon³).

¹ FAPES: Fundo de Apoio a Pesquisa do Estado do Espírito Santo. It means a financial found created by the Government of Espírito Santo state, Brazil.

² Year of the book version in Portuguese (Brazil).

³ By the coordinator and professor Carlos Dias Coelho (FAUL).

In the second part, the analysis will be presented about the typology of streets and their variations in the central area of Vitória (ES), from the creation of categories related to geographical location. Resources will be used as the historical approach to describe the background, analysis of the current floorplan base map (2009) with mapping technique known as solid-void and fieldwork. The limits of central area will be the official boundaries of the neighborhood named "centro" (Figure 1) with 94,43ha. This choice was made because it is rich space by overlapping times and forms, functions and experiences, as a source of interest for reflection through the lens of urban history.

The street

The street as a public space

Urban space is composed of various public and private elements. The public space is defined by being belonging to the community, accessible to everyone, anytime, including: streets, squares, alleys, boulevards, canals, beaches, bridges, squares, docks (Panerai, 2007: 79). All this set is organized on a network, hierarchical and continuous way. From all, the street is definitely the predominant element in the formation of the urban fabric due to the permanence of the trace over time (Panerai, 2007), the attribute of imageability in the construction of collective public image of the city (Lynch, 1997) and because it's place of sociability and hosts social events (Jacobs, 2000).

Conceptions of streets and city are very intertwined. Numerous examples of this relationship are part of the history of architecture since the origin of the city through the contemporary territory. Now, it's possible to remember Baron Haussmann when it comes to interventions in Paris in the late nineteenth century, promoting the opening of wide roads; Walter Benjamin when he writes about the same Paris portraying its boulevards, streets and characters in the twentieth century; and finally to the initial gesture of Lúcio Costa in the design of Brasília, in the XXI century. But there are so many others examples...

To Borthagaray and Ascher (2010), the street is also a space of living together, in a harmonic way or not: "What is a street? It is a road inside an urban cluster that serves specific or both, to cross a zone in the cluster to access places situated along or near this route immediately and to produce usable in various types of collective space activities. A street then assures at least one of the following functions: transit access (distribution) or received" (Ascher apud Bortagaray, 2010).

Since the eighteenth century, in consequence of the greater mobility of people and goods, the number of streets tended to increase. Throughout the twentieth century, the mobility increases even more and diversifies itself in such a way that the street becomes the main infrastructure in a large circulation system and, with more or less impact on the city, has different speeds, functions, templates, perspectives. This hierarchy of speeds generated avenues, streets, sidewalks, highways, freeways, exclusive, underground tracks. A few Brazilian municipal master plans, working with the idea of this hierarchy, classified the streets according to their flow capacity, width and location in the city as local, collector or arterial roads. Full of vehicles - buses, cars, motorcycles, bicycles, and its variables - the streets are also filled with people enjoying it at different speeds: walking, shopping, and chatting; older people, younger people; same people, different people. In the post-fordist city nor the pedestrian street or expressway tend to disappear.

In spite of all rich scenes and typologies, the street has been portrayed in Latin America in the last few years for its conflicts and dysfunctions, discussing their effectiveness and adaptation to the city (or vice versa), with much emphasis on the aspects of traffic engineering and statistics mobility. We believe that the street can and should be studied according to its urban form. The street cannot be divorced from the context in which it appears, and must be addressed as part of the urban fabric.

The street as a morphological element

In the second half of the twentieth century, in contrast to the modernist scenario that preached the "paradigm of the machine" as a processor of cities and buildings, has spread among urban planners and sociologists, the defense for everyday life, the mix of uses and the scale of human needs (Montaner, 2013).

It is in this context of growing sensibilizations for the local culture, starts to be systematized the studies of urban morphology, whose basic assumption is that the city can be read and analyzed for its ordinary physical form (Moudon, 1997). The production of the city is more than a distribution of objects in a territory organized around functions. The urban form is a set of architectural objects linked by spatial relationships and morphology "(...) is the study of the form of the urban environment at their outer physical parts, or morphological elements, its production and processing in time" (Lamas, 2000: 38).

Given the similarities and specificities of each of the major European schools of morphological studies - Italian, French and Anglo-Saxon origin - Moudon (1997) along with other members of ISUF⁴, fits three principles of morphology: the shape is defined three physical elements (buildings, plots and streets); the form can be read in four different levels (plot, street, city and region); the form can only be understood historically elements of which derives continually transform and there is an overlap.

With a historiographical approach, Lamas identifies three dimensions of urban form and eleven morphological elements of urban space, with the understanding and design of these identifiable in those, depending on the reading scale. This classification proposal builds on previous authors as Tricart and Rossi, have the argument that the reading of the city is done simultaneously at different levels and that the definition of scales - street, neighborhood, city - is key to any morphological study. In the sectoral dimension, or street dimension, Lamas identifies elements such as tracing, the square, the tree, the monuments, street furniture and street. In this context, the street is part of a set called "urban fabric or urban trace" (which can also be observed in urban dimension, or scale neighborhood): "[...] is one of the most clearly identifiable elements both in the form of a city as the act of designing. Based on a preexisting

⁴ It is an international organization created in 1994 to unite researchers of urban morphology -. International Seminar of Urban Form (ISUF). Official site: <http://www.urbanform.org/>.

geographic support, regulates the disposal of buildings and blocks, connects the various spaces and parts of the city [...]” (Lamas 2000: 99-100).

Also understanding the street as part of a whole, for Panerai (2007), the beginning of an urban morphological study should be done from the growth of the city related to the lines of force of the geographical territory. In his writings on urban analysis, this French author develops the definition of "urban fabric", in clear Italian influence, understanding this as a superposition of three key sets of elements: networks of roads, land subdivisions and buildings. Notes that the analysis of urban fabric involves the identification of each of these elements through the observing of the relationship between typology of buildings and urban form. In this approach, these elements together constitute the public space as opposed to bordering land available for housing, mostly private. Whereas the hierarchy and the role that roads have on the structuring of urban form, Panerai states that the design of streets appear geometries, regularities and repetitions and that this can be analyzed as well as the whole of routes from: i) relationship between plotting routes and geographical site: relief, soil type, flood zones; ii) role of roads in urban and regional groups; iii) geometric logic of strokes especially in monumental systems, and its relation to the history of land ownership.

With the premise that it is from the existing topography that draws the city (Lamas, 2000) and that there is a relationship between track route and site (Panerai, 2007), we intend to make an urban study of morphological characteristics of public space through the removal of layers of various components, beginning with the element "street".

Among the papers presented at the 1st Conference of PNUM⁵, held in Portugal/2011, Proença's work was taken as an example because his analysis of Lisbon's streets take the approach that the origin of the urban form is related to the *topos*: "Thus, we consider the public space of the street space bordered by adjacent private space; landforms Break, plans to scarps and water; or other distinct morphological elements of the considered public space" (Proença, 2011: 260).

In defense of the need to identify the diversity of the streets in the central urban area, Proença uses topography to define typologies, so-called: streets of ridge, valley, coast, coast and half climbers. This analysis considers as starting point the "natural streets" or those that mimic the geographical features of the site, comprising three phases: selection and collection cases; morphological analysis; rating categories.

Streets in the central area of Vitória (ES): a case study

"The city as an educational tool? It's not about whether it should be such a thing, but that cannot be anything" (Rowe, apud Proença, 2011: 259). By understanding the necessity of analyzing and constructing a type-morphic frame representative of urban form and considering that the study of urban morphology, when allied with the practice of urbanism, becomes a potential tool for the design of the city, this work suggests a morphological study of the streets in the central area of the city of Vitória (ES), based on the proposal of Sérgio Proença (2011) categories of type- morphic pathways.

The method for developing the primary stage of studies is also based on the theoretical frameworks discussed in the decomposition technique in layers and steps: record low plant all streets in the central area of Vitória sector from basemap with identification of typologies; record in transverse profiles and scale photographs taken in the field visit, each representing one of the typologies typologies, detailing elements of composition and allowing correlations between different types of elements studied. In this research project will be considered analytic

⁵ PNUM – Portuguese-language Network of Urban Morphology.

variable "form", with regard to the description of the geographic influences, full and empty site; width, scale and proportion of buildings and wide streets.

The territorial clipping covering the Centro neighborhood, called central area of Vitória, is justified by the fact that the morphological studies conducted focus in this area are rare; the fact contain a variety of cases, which enables a search rich in examples; and also because of having reliable cartographic databases.

Importantly, this work is located temporally in the present, so that no historical issues and transformations of the street over time will be analyzed. It is, therefore, an analysis that involves relating the types of streets found in central area of Vitória to its uses, thus knowing their morphological diversity for understanding the design of the city.

Conceptual cutout is based on the proposal type evidenced by Proença (2011) and the model of urban performance for the street proposal by Andrés Borthagaray (2010), in order to establish, systematically, the selection of cases. This selection followed the criteria relevant to the form and framework of the street in the immediate urban area associated with the characteristics of the physical site, thus defining the rating categories of analysis.

As Proença, the construction of a type consists of two phases: defining and meeting the common properties of the elements that make up each category, thus defining the type. From the observation of differences in the type, it is possible to observe variations in type.

Thus, goes the definition of categories and types identified in the central area of Vitória (ES).

Categories and types of streets

The classification of streets into categories and specific types observed implies understanding that the city, whatever it is, has specific characteristics that define and structure. These characteristics can be cultural, physical, social and economic.

Based on this understanding, we can infer that the city of Vitória has as elements that influence the streets of the central area topics related to physical site, since it is an area of rugged topography, formed by a large central mass, and soaked in water, the Vitória bay. The flat areas are due to the fact landfills in the nineteenth and twentieth centuries have been made, as shown in Figure 2.

The urban layout with topographic features is a dash of Portuguese vernacular urbanism, which the city of Vitória is heir, being one of the oldest cities founded by the Portuguese during the colonization of Brazil.

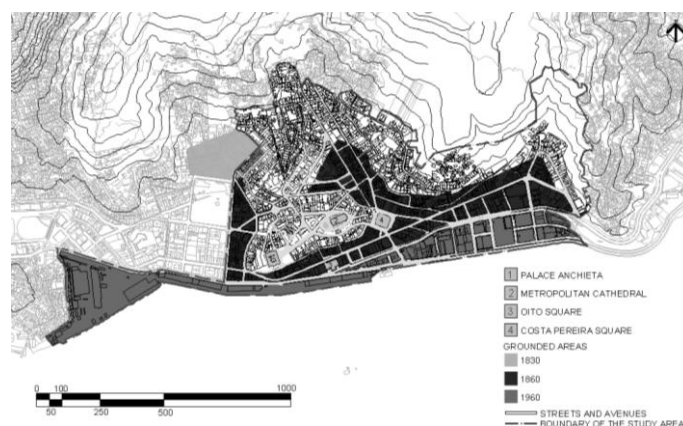

Figure 2. Gounded areas in the central area of Vitória (ES) (source: Ventorim, 2014).

Thus, it can be said that the streets of the central area of Vitória are divided into two categories of classification, according to its location: the physical site originally, composed this being the central massif of Vitória -, and area landfills.

From these two categories types can be defined. In the original physical site category, the types are: street slope and cross street. In the area landfills category, the types are: straight avenue and street corridor.

The street slope

The street slope, in the original physical site category, can be defined as one that extends on a single quota of a hill, or near quotas, requiring less effort in conceiving it, and also reflecting the influence of Portuguese vernacular mesh.

Figure 3. Coronel Alziro Vianna street location (graphic scale) (source: Marques, 2014).

Figure 4. Coronel Alziro Vianna street view (graphic scale) (source: Marques, 2014).

Figure 5. Coronel Alziro Vianna street (source: Marques, 2014).

In this type of street, buildings are located on the line of the street and are usually narrow. An example is the Coronel Alziro Vianna street, which can be visualized in figures 3, 4 and 5.

In the figures, it can be seen that the road is narrow, approximately 11m. It has a parking area of a side of the track. Two sidewalks are approximately 2m wide each in attempt to define the pedestrian path. However they are inadequate if observed, since the buildings are implanted in the line of the batches, and often with projections from other decks on the sidewalk; therefore, inducing pedestrians to walk on the road. Typological variations on the street slope are given by the height of the buildings and the presence of vegetation along sidewalks. In some of these constructions, there are two or three floors, while in other constructions; they are observed having five to six floors. The streets are narrow, giving access only to homes with restricted access, preferably residents.

The street slope ends up defining their uses. Due to its small dimensions, it mostly has the function of inhabiting. This situation leads to what Andrés Borthagaray (2010) says, namely, that the various functions of the street are more or less compatible with each other, depending on how it is presented, based on the morphological point of view, the relationship between the physical elements associated and, furthermore, the modes of transport.

The situation of narrow streets with narrow sidewalks, little stream of cars, some trees when possible and the relationship of the building with the lot, characterizes a type of street that is not shown to the city, but is preserved. It establishes an urban street performance that according to Borthagaray (2010), dissociates and divides the urban space as it presents its specific use - mostly residential - decreasing the chance that people other than those who reside there can cherish it.

The cross street

The cross street, also present in the original physical site category, refers to the connection between the high and low parts of the study area, interconnecting slope streets, overcoming gaps and topographic inflections (figure 6). The cross streets can also, connect the slope street and the street corridor, to meet in the transition from the original physical site from the landfill areas.

In general, the cross street type has similar attributes to the street slope: narrow streets, with minimum dimensions of sidewalk, presence of trees in just a few streets, less intense flow of cars, buildings on the lot tested with three floors, commonly giving the characteristic articulation of pathways between same attributes, or, organizers of transition, switching the type of hillside street to street corridor.

Thus, their morphological structure is directly related to the function of access, circulate-through, allowing residents of hillside streets to connect with the city, furthermore establishing a formal response to the occupation terms in areas of rugged terrain; besides receiving activities related to trade and local services in order to meet residing in the vicinity.

Figure 6. São Bento street location (graphic scale) (source: Achiamé, 2014).

For this reason, the cross street that presents a model of urban performance (Borthagaray, 2010) which tends to establish the union of urban space; is associated with the link function, attracting more transient flows of pedestrians and cars than the streets of the hillside.

The straight avenue

The straight avenue, present in the category of landfill areas, can be defined as one that extends longitudinally, throughout the study area, exceeding this limit, and expanding to other parts of the city.

The straight avenue features common variations of the typical characteristics, such as the presence of tall buildings commonly implanted in the tested lot with ten to fifteen floors, sidewalks on both sides, sparse vegetation present only in the squares bordering the avenues, three or more lanes of cars without parking, these variations establishes the heavy traffic of cars, besides the main bus stops in the study area. These features can be evidenced in figures 7, 8 and 9, which show the straight Princesa Isabel Avenue.

Variations in type present in the straight avenue refer to median plats, number of crosswalks present in each direction of the road/avenue, width of sidewalks, buildings with canopies that project on the road/avenue, or the presence of a boardwalk bathing bay Victory - integrating the city with nature. These variations on the type reinforce the idea that every town, and every street has its own attributes that give them identity, making them readable, and contributing to the understanding of the design of the city, associated with local characteristics.

Thus, it can be said that regardless of the variations found, its function is to connect the different parts of the city as well as receive various activities that meet the different sectors of the city. Usually having mixed functions, such as dwell (on a smaller scale), access, receive different activities related to trade and services.

In the case of straight avenues present in the central area of Vitória (ES), these activities are: i) households, banks, medical offices, institutional buildings on Avenida Marechal Mascarenhas de Moraes; ii) banks, consumer electronics stores, popular trade retailer in Princesa Isabel Avenue / Governor Blei; iii) retailer popular trade, banking and cultural buildings on Jerome Avenue.

Then we observe that the various activities presented in variations of straight avenue type also determines its urban performance, since the model of urban performance is defined precisely by the association between spatial form and uses and functions.

Figure 7. Princesa Isabel Avenue location (graphic scale) (source: França, 2014).

Figure 8. Princesa Isabel Avenue view (graphic scale) (source: França, 2014).

Figure 9. Princesa Isabel Avenue (source: França, 2014).

So, it can be said that the Avenida Marechal Mascarenhas de Moraes has a model of urban performance that divides the space because its features - connections from different sectors of the city, high flow of cars, activities related to specific services, such as medical offices, law firms, banks, institutional buildings - turns out to disperse the relations of social interaction, establishing them only in the squares that lie along this pathway. This is an example of what Margaret Pereira (2010) states: The Streets " [...] no longer places of conviviality, places to see and be seen and will be considered, especially as the main infrastructure increasingly fast 'large traffic systems'.

The Princess Isabel / Governor Blei and Jerome Avenues present a performance model of urban crowding, spatially integrates the city, the present flows of people, trade flow, communication, various activities related to culture.

Nevertheless, it is these pathways that normally occur the political and social events of the city, becoming stage of life events, once the largest concentrated flows of people, cars and transportation modes, are wide and connect the neighboring towns. In those moments, they become protagonists of the city.

The street corridor

The street corridor can be defined as one that connects straight avenues. It has templates, forms and layout of buildings compatible with those presented in the avenues that connect straight uses, but presenting the box narrow street with approximately 12m, 9m of which are in the range of cars bearing (figure 10).

Figure 10. Alberto de Oliveira Santos street location (graphic scale) (source: Neto, 2014).

The absence of trees, along with the (dis)proportion of buildings and the width of roads/streets/avenues accentuate the compression feeling of pedestrians and create strong gusts of wind, consequently, it becomes uncomfortable to stay and walk through. This situation, coupled with the lack of variety of uses - notably services - ultimately set it as low urban quality with exclusive access function, circulate-through, making as a channel the movement of people and cars.

Pursuing a model of urban performance (Borthagaray, 2010) which divides the urban space, since the uses and forms of layout of buildings make a distribution of urban space that separates the people from the space itself; in other words, only interested in looking at something specific in one of those buildings are using it as part of the circulation system of the city.

Conclusions

By the establishment of typologies for the streets in central area of Vitória (ES), one can understand the design of this part of the city, linking them to their uses and observing how the relationship form x function directly affects the way people behave in each place.

The four typologies found - street slope, cross street, straight avenue and street corridor - shape their uses by morphological characteristics, triggering models of urban performance of different street, which sometimes unite, integrate, and sometimes split, dissociate.

Read, understand and classify each of these types of street allows to conclude how they seem to be repeated in other parts of the city, establishing general characteristics of urban morphology in Vitória; and also contribute to, from the understanding of the dynamics found between form and function of streets, contemporary conceptions that can assess the strengths and weaknesses of each of the typologies, thus interweaves them with the new to continue the readability of city.

Studies and hypothesis on Mdina and Rabat urban form

Antonio Camporeale

Department of Architecture and Project, University of Rome “La Sapienza”.

E-mail: antonio.camporeale.7@gmail.com.

Abstract. *The study presented here deals with the theme of the reading of the urban form of the city of Mdina, the old capital of the island of Malta, and Rabat. The interest in the study of these two urban centers, whose fortunes are inextricably linked to structural reasons, arises from some geographical considerations. The island of Malta, in fact, lies at the center of the Mediterranean Sea, in a central position respect to cultural exchanges between the peoples who inhabited its shores and the resulting hybridization dynamics that have characterized its history. Dynamics that can be researched in Maltese architecture, built result of contributions and strong exchanges between the different cultural areas and during different historical periods. Mdina, with Rabat, still preserves its urban form, readable and comparable with other centers such as Birgu and Valletta. The analysis of its urban form aims to highlight some typical features of the Mediterranean: the presence and persistence of the house with a courtyard in the building tissues. It was also possible to advance a hypothesis, based on the method of study and reading of the alignments walls, identification of medieval pathways, advances and the size of the bands attributable to the built, of any planned reorganization by Romans, more evident in the tissues of Rabat.*

Key Words: method, urban tissues, typological process, urban organism, Mediterranean Sea

Chronology of major historical events

Mdina, the old capital of Malta, is situated on a promontory that juts out into the eastern side of the west plateau that defines the highest part of the territory of Malta, located about 200 meters from the sea level. An ideal location from the point of view of strategic groups of nomads who need to choose a safe place to settle and establish their own production activities, typical of primitive men. In fact, the city is protected on three sides by the height difference between the promontory and the valley it overlooks and which has full visual control.

The earliest records of settlements date back to the Bronze Age (1500-700 B.C.) and confirm this thesis quoted above: the discovery of a significant number of ceramics and the discovery of some stone blocks dating back to this period, that during the Middle Ages, were reused for the fortifications near the Porta dei Greci, suggests the idea of a little settlement that would have had a significant importance for the island. Given the archaeological evidence, we cannot exclude the possibility that this may have been protected, the less well from the south side, by a defensive wall. The transition from the Bronze Age at the next time is marked by the arrival of the Phoenicians (VII century B.C.). It is likely that they encountered the island in a totally fortuitous way: starting from the eastern shores and pushing towards the western part of the Mediterranean, which is physically beaten by them in trade routes, in search of new territories to colonize, the Phoenicians have easily occupied the island reaching the ancient Bronze Age settlement on the promontory of Mdina. “At some point in time between the 6th and the 3rd Century B.C., when Malta seems to have firmly under the control of the West Phoenician city of Carthage, a fortified town replaced the Bronze Age settlement on the Mdina Promontory” (D. De Lucca, 1995, pag. 3). It was probably the site of a Carthaginian military contingent pledged to defend the island from the continuous attacks by the Greeks from Sicily, and later by the Romans during the Punic Wars.

In 218 B.C. the island of Malta fell under the control of the Romans and the Phoenician-Punic Melith became Melite (or Melita). There are many archaeological finds from the Roman

period, but little is known about the urban structure of the city. In 535 A.D. the Byzantines took possession of the island: the Pax Romana was broken and returned to the constant fear, because of the attacks of the Berbers from North Africa and from the Italian peninsula. This general state of decay, which often has even led to the abandonment of entire settlements spread across the lowland, forces the population to return to their fortified enclosures. It is presumably what has happened to Melite: "the hypothetical creation of a Byzantine *Kastron* on the side of Mdina standing proud among the ruins of the ancient Punic town and containing a church and suitable residence for the civil and military Byzantine administrators is a plausible image of the fortified Byzantine settlement that emerges on the Mdina promontory in the early 8th Century" (D. De Lucca, 1995, pag. 18). The raids of the Arabs were followed until 870 A.D. when finally conquered the island and Melite became Mdina. Due to the almost total absence of information concerning the Arab period, is not possible to reconstruct the urban form that the city took after their arrival, but it is possible to imagine, for example, the presence of a place of worship as a mosque, inside the defensive walls. From 870 B.C. to 1240 A.D., the year in which all the Arabs were expelled from Sicily and Malta by order of Frederick II, the city of Mdina experienced a period of prosperity. As Idrisi, an Arab chronicler of the time, wrote: "Malta, a large island with a protected harbor open to the east, where there is a town (Mdina) rich in pastures, flocks, and fruits of all treasures." After the mid-13th Century, placed firmly under the influence of European culture and the Christian religion, this registering a considerable impact on the gradual transformation of the Muslim town during the course of 14th and 15th centuries hinged, of course, on the small Romanesque church standing as a shining light in the center of the town" (D. De Lucca, 1995, pag. 25). Conventual religious orders, such as the Benedictines, Augustinians, Carmelites, Dominicans and Franciscans, they build the great monastic complexes in the empty lands outside the walls of Melite.

From the social point of view, after the conquest of Sicily by the Spanish Aragonese, the island riched diverse cultures: the indigenous Maltese, Arabs, Greeks, Jews and Latinos joins the Sicilian nobility that, through the institution of the *Universitas*, administratively controls the new Maltese feud. For the defense of the city was designed to strengthen the system of fortifications already thickened by the Arabs: it was erected new walls parallel to the first on the south-west and it was dug the ditch. Particular attention has been paid to the design of the main entrance of the city: in this case you import the bayonet model, spread throughout the Mediterranean, so it prevents, through the imposition of built fronts on the route, the linear and direct access to the city center. "In this respect, the main entrance area of Mdina, with its statue of a pagan Goddess and with its small church of S. Maria della Porta, shops, stores and military trappings, must have offered the first greeting to the trader, the pilgrim, the farmer and the town dweller so that it could be correctly interpreted as a customs house, a passport office, an immigration control point, a market place, a place of worship, a reliquary of old traditions and a celebration of military power, all rolled into one spatial entity of enormous significance and physical strength" (D. De Lucca, 1995, pag. 33). The city was gradually set up as a place to seek shelter and protect themselves from the incursions of Berbers from North Africa, taken by force from the beginning of the fifteenth century. The interior floor plan is organized arranging themselves along the main route that bisects the city, dominated by the most important buildings and the headquarters of the Sicilian nobility in Malta.

Compared to the main path, the eastern part, where today stands the cathedral of St. Paul, home to government buildings, the representative architecture of a certain artistic value, while in the eastern part develops the typical residential fabric of the Mediterranean areas, formed by houses organized around a common courtyard. 1530 was the year of the arrival of the Knights Hospitaller in Malta. Landed in October in the port of Birgu, only in November, the Grand Master L'Isle Adam agreed to meet with representatives of the *Universitas* of Mdina. The reluctance to act this was due to the poor conditions in which the city of Notabile was fallen: semi-abandoned and adopted a system of fortifications now obsolete for new and powerful weapons used by the Turks of Suleiman, ready to go to the West. In addition, for the first few years on the island the priority was given to the same type of defensive adaptation with the

Castrum Maris, which was the first site elected by the Knights for their stay, albeit temporary island. The work began and continued at a slow pace, but fortunately finished in time to cope with the massive attack of the Turks and the subsequent siege of 1565. The form, and, more generally, the design of the new fortifications were based on projects developed by Italian engineers: the mighty ramparts who surrounded the city, joined in turn by massive walls, allowed to have a full view on territory and to aim their weapons at the enemy, covering all possible angles. The Italian engineer Gabrio Serbelloni, already former superintendent of papal fortifications, proposed to transform Mdina in a military camp: the proposed withdrawal of the south walls to cut off a good part of the fabric of existing houses and the construction of two large bastions angle. For unknown reasons these proposals were never implemented.

There are four operations of major construction, took place between the sixteenth and the seventeenth century, that have fundamentally altered the urban form of Mdina. The first of these concerns the construction of the Magistral Palace near the south entrance to the city; the second concerns the construction of the church and convent of the Carmelites on the site of the ancient church of Santa Maria della Rocca; the third is the expansion and reorganization of the Benedictine monastery, with the addition of a convent for nuns; the fourth relates the story of the construction of the Cathedral. Of course, being in the Baroque Age and considering the dependence on the administrative and cultural center of Mdina to Sicily, the forms and the architectural language was based on those that were spreading on the Italian peninsula through the greatest exponents of this period, Bernini, Borromini, Rainaldi, among many.

The tragic event of the earthquake of 1693 caused an inevitable slowdown in the construction of these four important works, as well as damaging heavily on the structural level. The reconstruction of Mdina is chronologically divided into two major phases: the first (1693-1722) covers the ecclesiastical architecture and was marked by the projects of the new Baroque Cathedral, the Palace of the Bishopric and the new seminary. The second phase (1722-1736) concerns the reconstruction of buildings, military and civilian, of Baroque palaces and of the new baroque gate of the city. And it is precisely at this time that Mdina takes the established urban form, still visible today.

After a brief French domination, in which Napoleon, sailing to reach Egypt, stopped in Malta for a couple of years plundering the relics of the value of the Carmelite Church in Mdina, in 1813 the island passed into the hands of the English. The institutional and economic center of gravity shifted to Valletta and its large port. "In 1850, the British colonial government had decided to transport to Valletta all the 90 cannons belonging to the Order that were mounted on the fortifications of Mdina, thus underlining a policy of transforming this historic war machine into a "silent city" associated with peaceful activity" (D. De Lucca, 1995, pag. 120). From the architectural point of view, even in Mdina enters the new artistic way of making architecture: the revival takes hold and transforms the facades of the old mansions in beautiful neo-Gothic or neo-Renaissance palaces (Palazzo Testaferrata, House Gourgon).

Luckily there will be no more substantial transformations in the consolidated Mdina late baroque structure, until today. The city thrives on tourism and a renewed focus on the restoration of its architectural gems helps to maintain the perception of its ancient history.

Interpreting urban aggregative organism

The choice of the city of Mdina and Rabat as urban centers to analyze in conjunction, with the scale of aggregation and urban organism, has matured whereas, on a regional scale, represented the central and hierarchically more important urban node of the entire island. With the shift of the capital to Valletta and the growth of the strategic role of the Grand Harbour, Mdina has lost its institutional function of representation, it has preserved its historical and artistic value, becoming in time the main tourist destination in Malta. Rabat, however, has continued to carry out its purely residential function, avoiding to specialize the urban tissues, if not for the presence of the large convent complexes.

These two urban centers have witnessed a common history and must be analyzed simultaneously.

Planned city. Hypothesis for comparison

The hypotheses on the origin of the ancient urban structure of the planned city of Melite have proved conflicting. The archaeological evidence, in some cases substantial, have given and continue to give valuable suggestions for the definition of urban structure that has taken during the past ages, but as a whole are scarce and still lack a systematic organization. They allowed, however, to be able to assume the presence of an early settlement already during the Bronze Age and compare it as a typology to that of Borg-in-Nadur, consists of houses constructed with sporadic piles operated into holes in the ground and protected where the natural conformation of the site would not allow it, with a massive defensive wall.

From the seventh century B.C. the Phoenicians begin to move toward the western shores of the Mediterranean Sea, and during one of these voyages of exploration it is likely that they stopped on the island of Malta. Now, to occupy it and make it a small colony, the step was short. With the arrival of these people more organized from all points of view, the settlement of the Bronze Age is replaced with a real urban core, in all probability, fortified.

With the conquest of the Romans (218 B.C.) Melite does not seem to have changed the urban structure imposed in the Phoenician-Punic. This hypothesis is supported by prof. Denis De Lucca in the book "Mdina. A History of Its urban space and architecture "(1997) excludes the possibility of a Roman planning on orthogonal grid. De Lucca instead supports the hypothesis of a Punic origin of the ancient Melite, availing of the literary sources, archaeological evidence which hitherto were available: the presence of remains in the foundation of a fortified wall dating back to Punic, identified by the excavations in 1994 by prof. Anthony Bonanno, inside the city walls that enclosed Melite, suggested the presence of an acropolis area on the upper part of the city, consisting of public buildings, administrative and religious, as distinct from a lower zone, occupied by the current extension of Rabat, mainly residential. De Lucca argues that "the urban armature of Punic Melita was based on an irregular system of planning that probably developed as a response to the natural contours of the terrain" (D. De Lucca, 1995, pag. 8). In support of this thesis, he also proposes a comparison with some sites excavated in Punic Sardinia as Tharros, Monte Sirai, sulci and Nora. A few years later, the hypothesis of the presence of the Acropolis in today's Mdina seems to be confirmed by the studies of Nathaniel Cutajar (2001): the alleged absence of archaeological layers dating from the Punic period (V-III century B.C.) which would indicate a relatively low housing activity of the area, over the previous period (VII-VI century B.C.) has to think of a public use of the same area, left open like a square. At the same time, however, the excavation of numerous pieces of wall, found in some rooms beneath the Cathedral, others escavated in Villegaignon Street, others remains discovered in the foyer of the seminary and in the Villhena Palace, strengthen the hypothesis, a few years first excluded, of the planning on orthogonal grid of Melite. In the doctoral thesis of the scholar David Zahra titled "A didactic itinerary of the historical heritage of Mdina" (2002) there is the first attempt to sketch the alleged Roman grid. Nothing has been produced rather than the area that stretched on the current Rabat.

Hypothesis of roman re-planning

The analytical work get start from the light path traced by recent studies on the subject and try to provide some additional insights that can be verified only with the help of a more thorough and systematic archaeological campaign. The reading and interpreting method adopted is the one defined by Gianfranco Caniggia. It first involves the identification of routes that shape the fabric and contextually relevant strips that determine their hierarchy. This is necessary for

understanding the way in which the fabric has been consolidated in the course of time, according to those general laws relating to a precise cultural area around of which Malta forms part, which is the Mediterranean. The basic instrument of the research is mounting architectural surveys of the ground floors of the buildings. In this way, having returned the most complete assembly possible of existing buildings in tissues, we proceeded to the identification of these orthogonal grids which define the possible overlaps of built that occurred at different times. Another important factor is the process of medievalization which generally invests the urban fabric, adapting to new cultural needs of the medieval period. All this cannot be separated and must be based on the broader historical record and traceable on archaeological evidence unearthed during the excavations.

The urban fabric of Mdina, in contrast with Rabat, is still enclosed within the massive defensive wall since the Phoenician occupation and reshaped according to the military technology, force in each subsequent period. Today it is structured on a main street with a north-south direction, Villegaignon Street, which connects the city gate with the bastion placed in an not-built area on the north side of the city. This trail overlooks the majority of buildings including specialized buildings as Palazzo Falson, Palazzo Santa Sofia, Palazzo Iguanez, the Convent and the Church of the Carmelites, the Convent of the Benedictines, the Giuratale Tour, the little churches of St. Agatha and St. Peter. In the middle of this axis, opens to the East the town square, on which stands the imposing Cathedral of St. Paul, from which it takes its name, and other specialized buildings such as the former Seminary and the Archbishop's Palace. The western side of the fabric axis, presents a totally different nature: it focuses, in fact, the purely residential fabric of Mdina, which developed along the structuring of St. Nicholas Street, which in turn is polarized in the Porta dei Greci. The secondary routes, orthogonal to the principal route, bud from these two main axis and in the transverse direction (east-west) structured the entire city.

Beyond the walls, the empty area of respect, defining a sort of hiatus, determines the distance from the urban center of Rabat. The route structuring the urban grid is detectable in San Pawl Street and seems to repeat the same direction of St. Nicholas Street in Mdina. Here the fabric is essentially composed of basic building type with the insertion of large specialized complexes of conventual buildings, occupying antinodal areas. It is obvious just by looking at the urban form of Mdina, the concentration of specialized buildings in the eastern than western area and also with respect to the fabric of Rabat over the majestic Cathedral, which abuts the Sacristy, are the former Seminary and the Archbishop's Palace. This could indicate the maintenance of civil and religious functions of the area in Roman times, where would host the temple of Juno, also indicating a probable continuity with the religious tradition of the Phoenician goddess Astarte and after the Punic goddess Tanit. In Rabat, it is conceivable the presence of the Roman Forum in the central area of the fabric, now occupied by a serial specialized building with conventual function. Through time, this spaces, and more generally, those that have specialized, for example along the walls and near the entrance gates of the city, are usually abandoned during the period of late antiquity, when the institutional and administrative structure of the Roman Empire begins to crumble. Over time, these spaces become clogged with specialized constructions (monasteries, markets) or remain unbuilt. Is the case of the site where it is assumed there had probably been a building for the games (amphitheater): in addition, the walls and routes, that just in the vicinity of the suggested site deform and bend, seem to confirm this view. Following the same observations, we identify the site where supposedly there was the Roman theater: it may have been built near the main entrance of Rabat, on the south side, in the urban node into which flowed the territorial routes that connected the city to the countryside, where we assume the existence an important gateway. Here, too, the shape of the curve constructed buildings would resume the typical semicircular shape of the auditorium. Among the few archaeological finds up to today, in addition to the common theatrical masks in terracotta, stands a tomb dedicated to a young comedian and lyre player from Pergamum died in Melite. These help to strengthen our argument. Another important investigative tool is given to identification of the orthogonal arrays based on the

cadastral: these showed a certain modularity of routes and allowed, adding them to the sketched "clues" proposed by D. Zahra, returning an orthogonal credible of the roman structure of Melite.

Overlaying this first hypothetical grid on the cadastral, we could find another phenomenon typical of planned tissues, the so-called "medievalization": during the Middle Ages, the hierarchical routes, such as via principalis and the via Praetoria, great roads with reports not comparable to the needs of the medieval fabric, are obstructed from the constructed facade to the center. It is possible to read these "advances" also on the fabric of Rabat. Another key element to the base of the study was the excavation of the Roman domus and other alleged residential buildings near the south western fortifications of Mdina. Discovered accidentally in 1881, consists of a large colonnaded atrium whose mosaic floor is kept in excellent condition and related environments that are arranged around it. This domus has provided the other possible arrangement of the orthogonal planned grid that has been taken into consideration. Putting all the information from a system we could return a complete and coherent plan of a hypothetical re-planning of Melite, took place under the rule of the Romans.

Abstract. *A scientific reading of the territorial structure of both municipalities of Guasave and Ahome, in northern Sinaloa, has been carried out starting from the urban analysis through three successive workscales: territory, city and quarter. In the first approach, the agricultural planning of a vast portion of the coastal plain where a hierarchical grid of roads and canals modulate the territory with high precision is detected. At the city scale, it is revealed the presence of natural and historic traces, that compete with the geometric rigidity of the territorial grid to configure the present urban fabric of Guasave. The Sinaloa river and the courses that interconnected the old Sinaloa missions of the 17th century are historical paths that become incorporated into the urban planning of the 20th century, where the development of the central quarter (Colonia Centro) acquires a differential character. The old core mission of the Nuestra Señora del Rosario Church generated, since the 1920s, a urban grid that follows the geometric pattern of the colonial city with square blocks on orthogonal axes deviated slightly from the traces of the agricultural macroplanning. It is flexible in any case, because settles into the plot divergent paths departing north from the church square and sets its limits to the natural accidents or historical traces.*

Key Words: North Sinaloa, Mexico, geometric colonization, agricultural territory, American colonial city, orthogonal and hierarchical network system.

Convenience in territory and urban form research in North Sinaloa

Within the framework of the International Architecture and Urban Planning Workshop 2014, held in Sinaloa, Mexico, managed by the INTHAB (Instituto Tecnológico del Hábitat) and sponsored by the State of Sinaloa and the municipalities of Guasave and Ahome, it has been given an opportunity to a group of architects and town planners from different European and Mexican Universities, to place the first contact with the cities and the territory of Northwest Mexico, and more specifically with the municipalities above mentioned.

The geographical factors of Northwest Mexico and the remoteness of the region in relation to the heart of the country have kept it for ages in a secondary position to the political, cultural, economic and social main dynamics that have been taken place in the rest of the territory of the Mexican Republic. We must consider that the state of Sinaloa is located in Northern Mexico's Pacific Ocean coastline, in front of Baja California Peninsula across the Cortes Sea, and it is also part of this region together with States of Sonora, South Baja California and North Baja California. The region (Ortega, 1999) is framed by the abrupt mountains of Sierra Madre Occidental that run on the South into the belt of volcanic mountains that crosses Center Mexico from West to East. Such geophysical conditions have always made difficult to access the area and have kept The Northwest in an isolated position. The mountain range has proven a major obstacle to the mobility of all of the groups that have occupied Mexico from the beginning of Spanish exploration and, particularly, acted as a physical barrier to who have held the power in the main cities in central Mexico.

For the majority of experts that have travelled to North Sinaloa to participate in the workshop, and specially, for those who came from Europe, the area was quite unknown because there are very few documentary references of the study of its territory and its cities in the circles of scientific production that European experts are used to attend. These published references of the research of the different stages of urban and territorial development of the municipalities of North Sinaloa where we focused our studies, however, do exist, although information is scarce and scattered, and very often is focused from non-technical aspects. Many studies are made under ethnographic or folkloric aspects and are confined to small local areas⁶. Urban and land planning and development have been carried out in recent times: the first half of the 20th century, and they were very distinctive for both Guasave and Ahome, as will be shown. Therefore, it is very interesting to open lines of research in its study but from a different angle and, in any case, based in a scientific methodology.

To put forward this process is necessary to undertake an objective observation in line with the present state of a world that is different from the one we usually find in the European or North American context. Herein lies its strength and originality, thus, in a first phase, that is concerned with this paper, the reading will be basically descriptive and will focus on the analysis of the morphology based on the geometry of the traces that define the territorial and urban structures, determining its layout, hierarchy and metric parameters. The start of this research is complemented by the outline of the context formed by social, economic and historical motivations that influence growth of cities and transformation of the territory.

Historic outline of the urban and territorial development of Guasave and Los Mochis

Guasave and Ahome are the most important municipalities of North Sinaloa, according to demographic, social and economic criteria. They are also very large municipalities⁷ (3.464 y 4.343 km² respectively) that are settled on a coastal plain crossed by the rivers Fuerte and Sinaloa that flow into the sea perpendicularly to the coastline. At the moment, the plain is used for irrigated lands, with fertile soils and presence of water distributed through large hydraulic infrastructures which has enabled the expansion of high-yielding mechanized agriculture, becoming a strategic activity for the national agro-industry.

Figure 4. Mexican Railways. Built and projected lines, 1881.

The creation of the port of Topolobampo and the construction of the railway that would link it to the US, unfinished until 1961, from the Atlantic coast (Norfolk, Virginia) to this port in the Pacific coast (Zonn, 1977), lead characters as Albert K. Owen to the Fuerte River Valley for the establishment of an agricultural colony in Topolobampo with American immigrants under the premises of the Utopian socialism in the last quarter of the 19th century (Ortega, 1987 and Moreno Rivas, 1992).

The most important work of settlers was the construction of the largest irrigation systems that were known in the Valley. According to Villaseñor Atwood (2001), under planning carried out by engineer Eugene A. H. Tays, they dug with spikes and blades a main canal, with length 11 kilometers, called Tastes canal, to carry the water from the Fuerte River up to the early settlement of Los Mochis, and also built secondary distribution canals and the cleared 1.500 hectares of wasteland grounds which were going to opened to cultivation (Ortega, 1999).

The initial trace of the village, that determines the core of the city at present, was guided by this set of canals, arranged in parallel to Tastes Canal, and following an approximate North-South direction. The canals are separated a distance of 1 km each other, alternating supply canals and drain canals. Layout gave expression to a functional optimization of irrigation systems, as well as to the most appropriate sizing for a crop field. Installation of sugar industry by Benjamin F. Johnston, in 1902 (Villaseñor Atwood, 2001), expanded the populated area due to the needs of the workers of the company, so commissioned an urban project that would guide the expansion of the city by following the traces already fixed by Owen and Tays. Street lines were traced perpendicular to the existing canals, separated by the same distance of 1 kilometer, generating an urban fabric of square blocks, very similar to the first proposal for the development of the colony in Topolobampo driven by Owen, although never carried out.

Figure 5. Plan of the first section of the Pacific Railway. Philadelphia, 1885.

Such planning did not follow the tradition of the Spanish colonial city in the sense that there was not a central place in the urban fabric called to host the public square around which would place the Church, the Market and the Government Palace.

Rather, the urban fabric enclosed a principal place that consisted on the plot of the sugar factory and its campus, in which were located the houses of the owners of the company and certain employees of first class; keeping this space closed and segregated from the rest of the population.

As it has been explained, the urban traces of Los Mochis came from the agricultural planning. As urban sprawl has been taking place, the agricultural elements that have been imposing the rationalization of the territory: canals and fields irrigated by them, have been transformed into streets and lots as they were being phagocytosed by the growth of the city which has been extended as oil slick, though profiled by the pattern of 1-kilometre square, to acquire current proportions of about 4500 hectares.

Until Federal Plans for agricultural planning are not taken in the decade of the 40s of the 20th century, Guasave and Los Mochis are listed as different worlds. The agricultural development was accompanied by the construction of large strategic infrastructures of transportation in Northwest Mexico. That programme has the inauguration of the highway Mexico 15 in 1955 as a culmination. Up until that moment Guasave and Los Mochis had traveled different paths despite having the same economic base in an important agricultural development.

Figure 6. Plan of municipality of Guasave. Technical Cadastre Office, 2001.

Reading of the urban and territory form: Guasave and Los Mochis

A scientific reading performed is extended to the territory between the municipal capitals of Guasave and Los Mochis, and goes downscale up to focus on the town of Guasave, completing the process in the study of urban form of the historic center. So that, from this point is developed a methodology of urban analysis through three successive workscales: territory, city and quarter.

Territory scale

On the plain between the towns of Los Mochis and Guasave, a large hierarchical mesh of roads and hydraulic infrastructures modulate the territory with great precision.

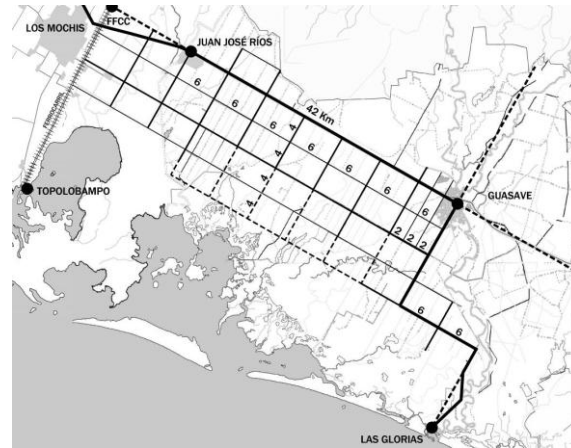

Figure 7. Planned structure of the territory. Own elaboration. Guasave, 2014.

In a first approximation, it is revealed the geometric colonization of a vast portion of the territory. It derived from agricultural planning started from the land reform of Lázaro Cárdenas in the late 1930s that opened the coastal plains of North Sinaloa to intensive cultivation. It also meant a major reorganization of the structure of ownership of the land because achieved the distribution of the major latifundia of the valleys of Fuerte and Sinaloa Rivers (Ortega, 1999), through the location of a large cloud of Mexican Collective Ejidos and the formation of agricultural colonies.

The Federal Highway Mexico 15 runs parallel to the coastline with an approximate orientation from NW to SE (slightly deflected from the orientation of the main grid which guided the growth of Los Mochis area), and is plotted as a straight line that connects the main urban centers of the region because the plain relief does not impose topographical restrictions that could break the trace in about 60 km. Only in the surroundings of Juan José Ríos town, the line takes a slight angle to reach also straightly to Los Mochis.

The mesh is constructed from parallel and perpendicular paths to the main road, and is structured from the cell base of 1 x 1 km square, the same which was adopted for planning urban development of Topolobampo and Los Mochis, that were agricultural developments originally. The hierarchical mesh extends to a length of 54 km and is about 20 kilometers wide.

The elements that compose the grid are linear infrastructures being the referred road of two carriageways the main one. It is recognized the higher order of the base module 6 x 4 kilometers, bounded by the main canals which run alongside traffic roads, which is divided into lots of 2 x 4 kilometers delimited by lower ranked irrigation canals. These are, in turn, divided into 1-kilometre square sub-modules whose limits are even smaller roads and ditches. The territorial structure is very strong and although is interrupted to accommodate the natural courses of rivers that cross the territory, these discontinuities only affect the geometry of the sub-modulation, and do not diminish the strength of the geometry. The main pattern overlaps and commands the constellation of rural villages (known as “Poblados”) of the municipality of Guasave, which are counted in a number close to 450. The majority of the Poblados were born under the structure of the Ejidos, whose inhabitants a piece of ground was assigned for cultivation as well as a plot to establish his dwelling in it, as Juan José Ríos in 1955 (Ramos, 2000); or from the urban consolidation of work camps, as Batamote in 1956, that were in charge of the construction of the large hydraulic infrastructure of the territory.

City scale

After focus the reading at the scale of the city of Guasave, it is revealed the presence of natural and historic traces, vying with the strength and rigidity of the territorial pattern described above, to configure its urban fabric. Among the natural ones stand out the course of Sinaloa River and

Ocoroni Stream; and among the last ones, the urban area of the original mission around the Main Church of Nuestra Señora del Rosario is barely perceptible; as well as the path network that start off from this point, that probably connected all the Mission Pueblos settled along the stream of Sinaloa River. Similarly, the first canals dug around the urban core to convey the waters of Sinaloa River to the crop fields next to the village, before it became the capital of an independent municipality. All that elements are constituted as the traces that are assimilated in its urban growth, that differentiate and sequence the stages of expansion.

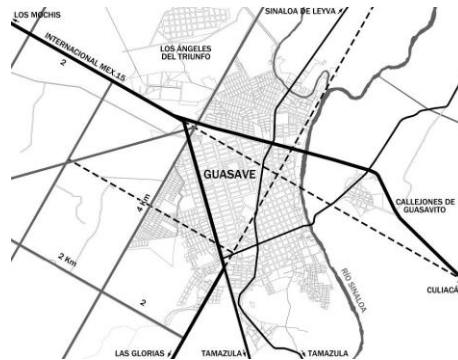

Figure 8. Urban development of city of Guasave. Own elaboration. Guasave, 2014.

The first planned development of the urban core, conducted by the authorities of the new municipality established on 30 November 1916, is known at present as Colonia Centro. It acquired a differential character in relation to the rest of the urban expansion because supposed the expansion of the old Misión core in a historic moment prior to implantation in the territory of the great geometric pattern of water infrastructures that rationalized the plain from the 1950s. It was created a urban fabric that was different from the one that was going to be generated subsequently in hand with the agricultural macroplanning, which will be specifically discussed in the next section. The above mentioned 2 x 4 kilometers territorial sub-module, precisely the one that is at the East end of the grid that already limits to the course of the Sinaloa River, penetrates into the town and imposes its traces on it. The main pattern along with the main diagonals of the mesh, are translated into an ordered disposition of canals, paths and drains that are called to organize the urban growth.

The defining elements of the sub-modulation of the territorial mesh itselfs constitute the West and South city urban limits, while the diagonal canal, almost coincident with the bisector angle of the Northern sub-quadrante of the mentioned 2 x 4 km module, is the main trace that orientates a new reticular mesh which is destined to consolidate the urban fabric produced from the 1970s in the extension of Guasave to the West of the Colonia Centro.

City core scale

As we have seen, the settlement of a small riverside village is conditioned by the presence of Sinaloa River. This primitive location is where a Jesuit Mission settled, a few years after, in 1608. According to Ortega (1999), Sinaloan and Sonoran Missions respond to a specific type of urban settings with a center where was situated the temple, which was the main point of the common life, together with the atrium, the cemetery, the belfry and the missionary house, all located in front and by the sides of the temple. Adjacent to the atrium, the main square served as a meeting place and around it, huts inhabited by Indians were lined. Beyond there were crop and grazing lands and pastures, forming perfectly delimited enclosures. The paths that connected the sinaloan missions form the historical road network that are incorporated into the urban planning of the 20th century, as it seems to be guessed regarding the Fig. 9. The first extension is developed under the geometric pattern of the colonial city with square blocks on orthogonal

grid; although its orientation is governed by the position of the old core mission: the Main Church of Nuestra Señora del Rosario. The axes of the religious building are slightly deflected in relation to the axes of agricultural macroplanning. The first ones guide an urban fabric that has been consolidated since the 1920s, presumably to the North of the current Street Doctor Luis García de la Torre whose eastern end wades the Sinaloa River. Its area is clearly confined, therefore, by the city of the 1920s, to the South, by the Sinaloa River, to the East and by Doradito Canal (now Central Boulevard), to the West. The mesh has a different metric to our known cases since its origin seems not to come from the rationalization of agricultural land. It also presents certain peculiarities. The regularity of the plot is based on the 100-meter square block, with 20-meter road section that seems accentuated by recognizing higher-order modules, super-blocks of 4 x 4 basic blocks. These higher order units have a dimension of 480 meters by 460 meters, next to the 1/2-kilometre square module, sub-module of those already used in Topolobampo, Los Mochis and in the agricultural planning of the territory. The mesh, however, has some flexibility because is defined in the urban environment and is adapted to the particular circumstances that the preexisting elements impose. From East to West, one block of 80 x 100 meters is included in every super-module that causes the undefinition of this higher order with pure square geometries. A row of these blocks arises in the pattern to accommodate the divergent paths that depart northwards from both long sides of the church square; and this narrower block appears repeated on the adjacent super-modules. We have seen that the limits of Colonia Centro are marked by natural accidents and historical traces. They abruptly cut the grid on the perimeter which is formed by triangular or trapezoidal plant blocks generating sometimes sharply angled chamfers.

Figure 9. Urban structure of Colonia Centro. Own elaboration. Guasave, 2014.

Conclusion

At present, the territory of Guasave and Los Mochis appears characterized by elements that define a regular and potent geometry; because they come from the rationalization of the land for intensive agricultural exploitation. These frames also condition the urban growth of the main towns which adapt to them formulating urban fabric and block metrics on the basis of the lower sub-modules of the main agricultural structures. It appears, however, interesting peculiarities as the case of Guasave primitive core and its first extension, opening research paths towards understanding the territorial and urban structures of the Missions era and towards the study of planning, genuinely urban planning, that was held, certainly in North Sinaloa, as was the development of Colonia Centro.

The memory of informality: the typological cycles in the self-built environment

Milton Montejano Castillo

School of Architecture and Engineering, Instituto Politécnico Nacional, Mexico

E-mail: mmontejanoc@ipn.mx

Abstract. *Informal or self-built settlements are concentrations of dwellings, built without compliance to official norms or urban planning. Today, it is estimated that there are approximately one billion people living in these conditions. This represents about one third of the world population living in cities today. Of crucial importance to understand these agglomerations is to capture their changes in time. However, such a task represents a challenge because these settlements are rarely documented in records or official sources. An attempt to track these changes based on the example of one of these cities: “Ciudad Nezahualcóyotl”, a one million people city, that during the last fifty years has been informally developed as part of the Metropolitan Area of Mexico City. Such a method is based on the identification and analysis of the typology of dwellings and their transformation through the time. Based on empirical evidences, we may say that morphological changes in informal settlements do not occur at random or chaotically. Rather, such changes are susceptible to be explained and traced back at the urban scale, by means of the observation of building types and the logic of changes they follow in time.*

Key Words: informal settlements, typology, consolidation, Mexico City.

The informal city and the morphological analysis

Traditional studies of urban morphology are based on the idea that certain rules of transformation over time dictate changes to the fabric, and that the organization and development of the fabric are not random, “but follows laws that urban morphology tries to identify” (Levy, 1999: 79). In his article, at the end of the last century, Albert Levy asked also the question, if such logics and laws were susceptible to identify not just in historical fabrics, but also on *modern urban fabrics*⁸, for which new tools of analysis were required.

Fifty years after this publication, the same question remains as relevant, because new types of cities and urban forms arise. One of this new urban agglomerations is the *informal city*, that “comprises the *slums* of the developing megacities, where the informal sector has its base; where services are poor or non-existent; and where residents are invisible to legal status systems” (Un-Habitat, 2003:23).

Quantitatively, this type of city represents a very extensive phenomenon. By 2003 it was estimated that about one third of the world urban population (approximately one billion people) was living in dwellings built without compliance to official norms or urban planning, and growing outside the conventional urban and constructive systems around the world (ibid, 2003).

After many decades of politics and actions used to tackle the phenomenon of informal urbanization, today the strategies to improve the livelihoods of slum dwellers are manifold: these include improvements on transport, generation of employment, empowerment of the inhabitants and improvement of the municipal finances, among many other strategies.

Spatially, allocation of resources to poor areas requires a geographical map of poverty. However, such a task represent a challenge because these settlements are rarely documented in records or official sources. Moreover, the urban fabric produced in the informal city is not

⁸ Levy describes the elements of the *new urban fabric* as completely autonomous, where constructed space no longer corresponds to the plot; where there is no longer a clear relation between one building and another, and between buildings and streets or open spaces (Levy, 1999:83).

simple and the social structure in irregular settlements is far from homogeneous within a single city or even within one settlement (UN-HABITAT, 2003:169).

The conditions described above have given rise to a series of attempts to map poverty, even facing the scarcity of official sources or census available. Informal settlements have been interpreted then as “urban texture” with the purpose of correlating morphological patterns with poverty (Barros and Sobreira, 2005). This concept is based on the quantitative analysis of the surface and configuration of the buildings as well as the internal emptiness or voids between buildings. Hence, the results based on the use of satellite images argue that the urban texture of informal settlements can be analyzed in terms of fractality and lacunarity. That is to say, informal settlements contain morphological characteristics which can also be found in the nature, properties which indicate a hidden order. In this sense, an estimation of the population density or the spatial patterns of informal settlements could be obtained from remote images, offering new possibilities for a mapping and classification.

Informal settlements have been also the focus of some morphological analysis at the scale of the building. A practical utility of this approach is the recognition of the design qualities of the informal settlements regarding the design solutions for the local environment. Such an analytical framework seems to be feasible, if we think about the informal settlements as a process and product of vernacular architecture (Rapoport, 1998: 351-377).

Considering the questions above, the field of urban morphology stands here as an opportunity to develop new tools of analysis based on the physical qualities of the territory. The objective then, is to show the main findings of a method to unfold the internal spatial differentiation of informal settlements.

Such a method should link the scale of the plot to the scale of the city. But most important, this tool should be intended to be based on non-skilled human resources or sophisticated data. In fact, information gathering about informal settlements (enumeration or mapping) is in many cases produced by the inhabitants themselves⁹ (Patel, 2012:3-12).

The informal construction process

In Latin America, informal settlements appeared mostly as a consequence of the rapid urbanization and industrialization occurring after World War II. In 1930, most of the population still lived in rural areas, whereas by 1980, over half the population lived in urban areas. This was due mostly to natural growth and rural-urban migration. In addition to this growth, there was a rapid social polarization that was reflected in the real estate sector.

Due to low wages and the precarious nature of economical development in real estate sector, housing for the working class was not a priority. Therefore, the urban poor acquired their housing in their own way, in some cases subdividing mansions abandoned by the wealthy. This was the case in some areas of Mexico City. Alternative low cost dwellings arose, with people building their own squatter dwellings and later on the quasi-legal purchase of land from people who illegally subdivided their property (Ribbeck, 2004, 35-43).

These settlements are spread throughout the urban area. In many cases, they are located on land that is inadequate for housing due to flood risks or steep hills where building is difficult and infrastructure is costly to provide.

As opposed to “formal” urbanization, which begins with an urban plan, a legal delimitation of property, infrastructure and services necessary to complete the building, informal urbanization begins backwards. First the informal settlers build the dwellings, then bring in the infrastructure and finally define the ownership. At the same time, in the structures as such, a series of constructive stages can be observed (Ribbeck, 2002; 2005: 159-171).

The network of streets in spontaneous urbanization is carried out in an orthogonal manner ensuring a relatively rational distribution of infrastructure. Within this orthogonal scheme, the

⁹ For more information, see the special issue of the Journal *Environment and Urbanization* 2012 24.

dwelling is developed with some freedom since there are no formal restrictions that limit or control the growth of the dwelling as such.

The building process can be carried out in a fragmented manner but a patio for lighting and ventilation purposes is generally used. The construction is usually based on a minimal concrete structure with modular cells measuring about 4 by 4 meters (about 12 by 12 feet). These are grouped either linearly or serially for a flexible use of space to accommodate: sleeping, living, a room for the children, shop or a storage area. Another use is for business: a small store, a micro-factory, or rooms could be rented out and thus become an important source of income. The continuous construction of cells doesn't follow any design scheme or floor plan; it is rather a cellular kind of growth.

Based on the principles of informal dwellings, a house develops by following a step-by-step growth pattern. It generally begins with the use of temporary materials. Growth usually begins in the form of an "I" or "L", usually with the creation of a multi-use patio. As more and more cells or rooms are added on, the patio usually disappears and is transformed into a hallway. The dwelling begins to grow vertically once about 2/3 of the surface has been built on. As the dwelling grows upward, windows are opened up for lighting and ventilation as the open inner areas have been drastically reduced.

A family's need for space can reach a limit and at that moment the dwelling stops growing or falls into disuse because some family members have moved away. In other cases, the dwelling continues to grow, not for the family, but to be sublet out to other families. In this case, comfort is drastically reduced since per person space has diminished and illumination and ventilation have also decreased.

The informal construction cycle stops with the complete substitution of the dwelling. This occurs in older settlements (around 50 years old), although it is also seen sporadically in younger ones when these are located in strategic areas- on main streets or in downtown areas.

The informal city Nezahualcóyotl

An example of the informal construction process is "Ciudad Nezahualcóyotl", a 1.1 million people city which during the last fifty years has been informally developed as a part of the Metropolitan Area of Mexico City. Ciudad Nezahualcóyotl (short named "Neza"), originally informal settlement, has been self-constructed over the last fifty years and with 25 km² and more than one million inhabitants, is one of the largest and most densely populated informal settlements in the world (see Figure 1-a).

Figure 1a. Location of Ciudad Nezahualcóyotl, Mexico City (source: Castillo).

The city locates on the former Texcoco Lake, which at the beginning of the 1950s had several kinds of proprietors including common share, federal property, national property, and private property. Amongst this confusion, the lots of land of the old Texcoco Lake were further fractioned into smaller lots grouped in neighborhoods or "colonias" and placed for sale by illegal developers, with prices decreasing in direct relation to the distance to Mexico City. In spite of the existing confusion regarding the property of land, the Mexican Government had

been authorizing developments since 1949 (García, 1992). Some of these developments needed to be regularized as the allocated lots of land were already sold and occupied.

Due to the massive amounts irregularly plotted lots in the old Texcoco Lake region (near to four thousand hectares), in 1958 a Law for Developing of Land of the State of Mexico was issued. Through this law the developers were forced to adapt their projects to certain urban planning measurements, such as the donation of surface for green areas and public services of at least 10% of the total surface area. Further, the law required streets with minimum width of 12 meters and a front of at least 10 meters.

A surface area of 4,000 hectares, bordered to the North by the remains of the Texcoco Lake, to the East by the Chimalchiuache mountain, to the South by the Zaragoza Avenue, and to West the latter built Peripheral Circuit.

The land surface was divided in more than 25 modules or “mega-blocks” of approximately 1 km by 1 km (see Figure 1-b). Free spaces for public areas for urban equipment such as public schools, clinics, markets, and churches was appointed towards the interior or perimeter of the mega-blocks. These public areas had the purpose to concentrate services for each mega-block. There was no space left for a main place or a recreational space for the whole city; the only place of this type was a space appointed to lodge the administration of the City. Each mega-block held approximately 90 blocks, and each block was divided into roughly 50 lots of land each, which had an average measurement of 150 m² (9 x 15 meters).

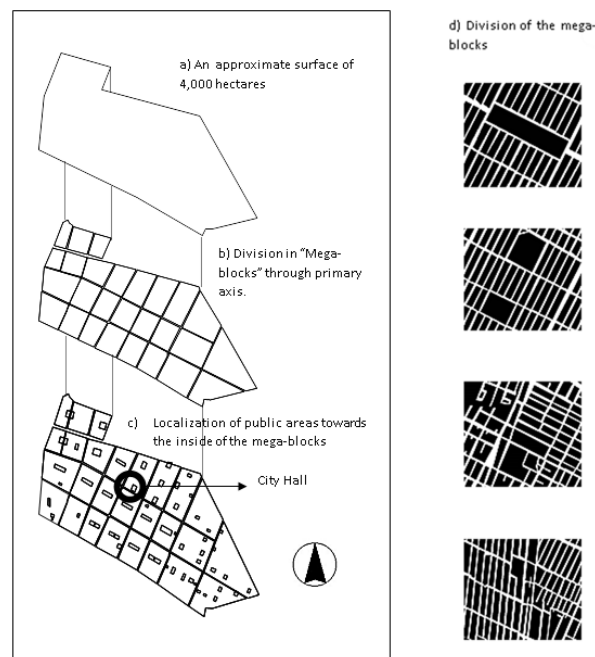

Figure 1b. Parceling of the Nezahualcóyotl City and the types of Megablocks (source: Castillo).

The parceling out of the land was not repeated in the same pattern for the entire surface. For some of the areas, which had already been occupied, the developers refused to donate lots for the creation of public areas. This resulted in mega-blocks with variations in the regularity of its plotting and in the distribution of their public areas. Some mega-blocks were created with spread public areas, and other mega-blocks were created with big orthogonal zones that measured roughly 500 x 120 meters. Other mega-blocks grouped their public areas in one, two, or three squares that limited the avenues. There was also the creation of mega-blocks with the primary characteristic of the planned division for commerce and public services in public areas of different location and surface.

After almost three decades of social struggle for services and legalization of plots, this large informal settlement finally became a municipality in 1962. With its legalization, a massive program for the construction of infrastructure started, and the inhabitants continued with the self-construction of their houses.

As a first step to document an intra-urban differentiation in Ciudad Nezahualcóyotl, a graphical documentation, of the dwellings was carried out. To undertake this study, the facades of 43 blocks from different parts of the city were first selected and photographed. Once photographed, the facades of each building were organized into blocks of drawn -approximately 1800 buildings. As a further step a typology of dwellings was defined. Some of the main typologies are in the following described¹⁰.

Buildings in process of consolidation

After 50 years from the beginning of its urbanization, one can still see the first steps of the informal building in Ciudad Nezahualcóyotl. At this stage the physical structure is the easiest to see: a 4x4 modular concrete skeleton, filled with bricks or stones of concrete. This structure may be covered with a concrete or a slightly sloping roof which outlines (when looking from the street) the limits between the room and an internal courtyard.

When the house acquires window openings, a visual relation to the street begins. The perforations may be placed on one or both sides of the door. The complete façade remains either without or only partially plastered. Particularly the corners may be used for small commercial activities. Due to the fact that many walls had not been completely finished, they are often used for commercial or political advertising.

The building process of the second floor of the informal building doesn't occur automatically but rather one step at time. An approximately 4x4 meters wide room on the second floor signalizes where the densification process begins. This room is built on one or the other side of the plot (see Figure 2). Sun exposure or wind direction seem to play no role in deciding which side of the plot will be built; even in contiguous houses the verticalization may start in opposed directions. The second floor may be illuminated and ventilated through the street or through the courtyard.

Later on other rooms are added to the already existing room on the second floor. The new rooms are all aligned on the same side of the house. Once the new rooms are built, the house is plastered and colored and an "L" form defines the new façade.

Especially if the first floor of the corner building is occupied by commercial activities, the densification of the plot develops faster. If this occurs, the entire second floor is built at once, leaving no internal spaces nor a courtyard. In this case half of the building that is plastered is used as a store, while the other half remains under construction.

Consolidated buildings

A saturation of the front side signals that the densification of the rest of the plot is still in progress. The new rooms on the second floor may be built on any place on the plot. The built spaces are articulated by balconies or terraces. With this densification the courtyard begins to lose lighting and ventilation.

Saturated buildings

To the original "L-shaped" façade other rooms are adhered in form of patches. On the top of the house a third floor may begin to form with a provisional iron-sheet roof supported by columns,

¹⁰Due to the fact, that the commercial activities are present in practically all the types of buildings, the mixture of land use was left aside in order to reduce the complexity of the categorization. For detailed information about the building typology, see Montejano, 2008.

precisely the same manner as in the very beginnings of the informal building. With time the iron sheets are replaced by a concrete roof and the skeleton is filled with bricks. In other cases the densification takes place but the courtyard remains and as a result the façade takes the form of a small tower.

Figure 2. Building typology in Ciudad Nezahualcóyotl, Mexico City (source: Castillo).

When the room on the top receives a plaster coating, the building and the perspective changes: the building seems higher because of the small erected tower. The building gets a different expression too, a different one than that of a house. Small windows on the top signify a complementary use.

Multi-storey buildings located on the corner of a block differs greatly from those located in its center. The ones in the middle are used as housing apartments with a repetitive typology, whereas the corner buildings are occupied by dense commercial activities, this in turn influences the size of the doors and windows, in order to take maximum advantage of the location.

The limit of the construction density seems to stop at the fourth or the fifth storey. This type of building may be built traditionally or professionally. The fourth storey may be built all at

once or it may start with a small room which develops step by step just as in the previous examples.

A morphological characterization of blocks

Based on the literature and the empirical evidences, so far we may conclude that the process of informal construction corresponds to a *typological change*, where ‘alterations and changes to existing buildings form the basis for a new concept of the house or leading type which, in turn, form the basis for the construction of new houses. Further alterations to those new, as well as previously built houses form the basis for another change in the leading type and so on through cycles of building’ (Kropf, 2001:33).

Departing from this assumption and in the absence of official records to measure the speed of change of the buildings, the approximated age of the city¹¹ was compared to the “morphology” of the blocks. To make this, and according to the typology described above, the facades of 43 blocks were categorized per block (approximately 1800 facades, and divided in three types of buildings: “buildings in process of consolidation”, “consolidated buildings” and “saturated buildings”). The result is a map indicating the proportion of buildings inside each block (see Figure 3).

As is seen in this figure, the majority of blocks consist mostly of “buildings in consolidation” (the white segments of the chart) which are mostly concentrated in the south-eastern and north-eastern areas. In other words, in the younger settlements areas, whereas in the old settlements area this proportion is lower.

At first glance, one would expect the different blocks to have the same quantitative distribution of buildings’ types. However a closer inspection shows that they don’t, in fact they were different and the proportions of building types varied in each block (chart). For example in some blocks, three quarters of the chart were white: in others, half of the charts were gray. This leads to the conclusion that one can further differentiate the types by finding “common denominators” (typical mixtures of buildings between the blocks), and for this reason, they have been organized according to three categories.

Low consolidated Blocks. These blocks consist of approximately three quarters of buildings in process of consolidation and the rest consists of consolidated buildings. Multi-storeyed buildings are seldom.

Semi consolidated Blocks. Approximately a half of these blocks are buildings in process of consolidation and the other half consists of consolidated buildings with a very few proportion of saturated buildings.

Consolidated Blocks. These Blocks contain the highest proportion of saturated buildings or buildings in a post-consolidation stage. The consolidated buildings represent from 25% to 50% and the rest (in variable proportion) consists of buildings in process of consolidation.

In order to geographically visualize the types of Blocks found in Neza, they were represented by points with different color (see Figure 4). Finally the points of the same color were joined. This way, it can be distinguish between six clusters with different levels of consolidation: three red clusters, two yellow and one orange.

Results

It can be seen that in a span of 50 years, Consolidated and Semi Consolidated Blocks can be found, whereas, in areas with an approximate age of 25 years, Low Consolidated Blocks are typical. An interpretation of these results makes necessary to consider the historical context of

¹¹This information was documented from aerial photographs.

the settlement and, all above, the relationship between this settlement and the growth and changes of the Megalopolis.

The red clusters, which are mostly comprised of *Consolidated Blocks*, were found in 3 different locations, which are describe in the following.

a) This area was developed before official restrictions on the size of plots, streets and public areas were introduced. For this reason, this area has a rather irregular spatial structure: there is no a clear hierarchy of streets; the streets are not parallel to the rest of the city and public facilities are not equally nor clearly distributed. Functionally, the type of commerce which developed in the area is relatively traditional and specialized: commercial strips of clothing, auto parts and a meat market, whose merchandise are introduced to the city by large trucks or food containers which pull over in the periphery of Ciudad Nezahualcóyotl, along the metropolitan ring

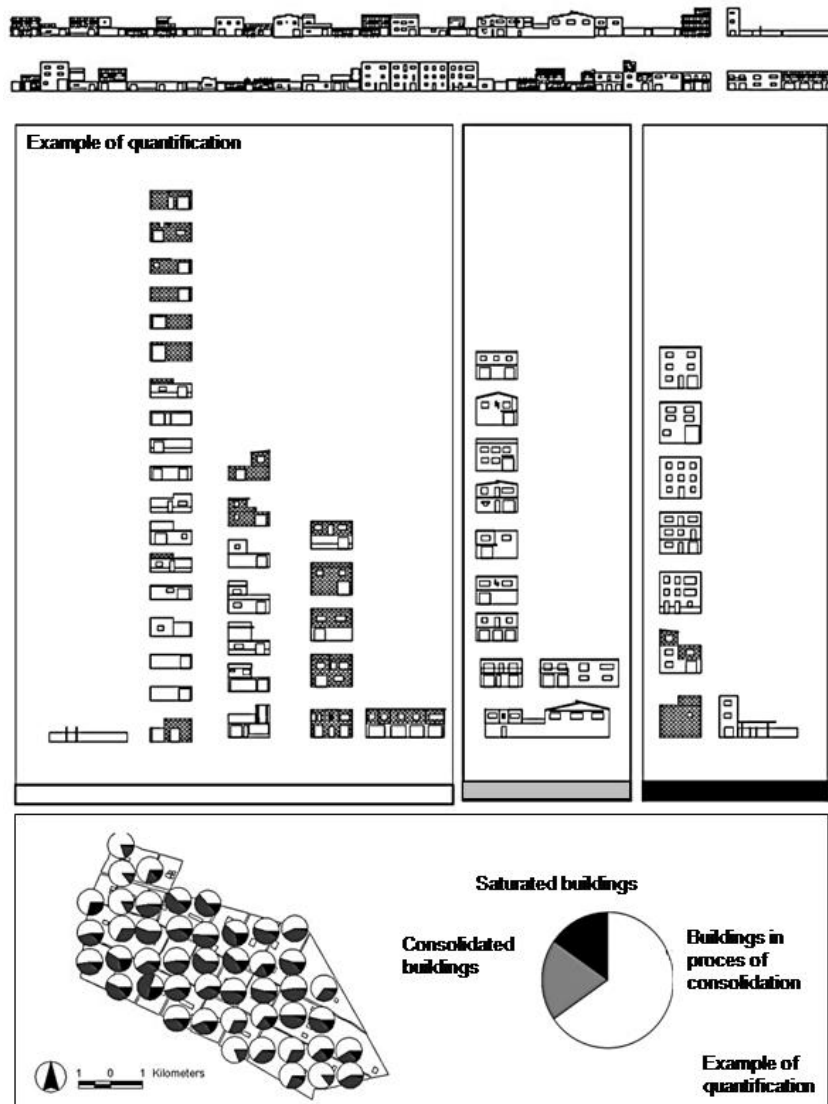

Figure 3. Quantification f building typology on the blocks (source: Castillo).

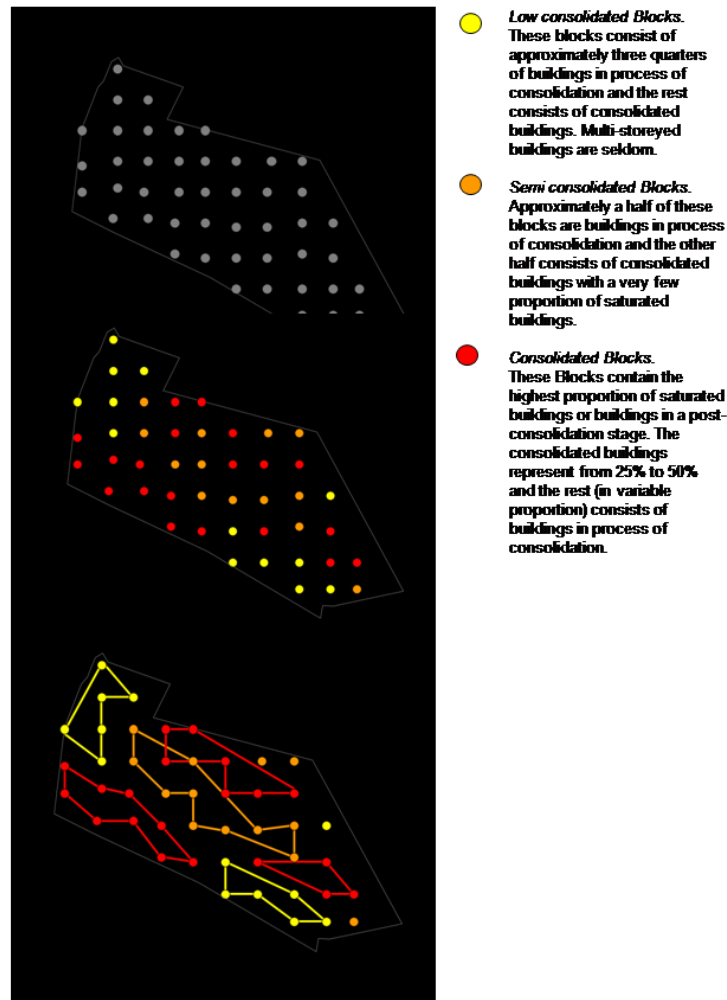

Figure 4. Mapping of block Typology in Ciudad Nezahualcóyotl, Mexico City (source: Castillo).

b) An area that has a regular spatial structure. It was occupied by the end of the 1960s. The connection between this area and the Metropolis is the best of all the areas. The avenue which goes through the middle of the area has the largest section of all the avenues and these connect Ciudad Nezahualcóyotl to the metropolitan ring. The accessibility here was further increased thanks to the construction of a metro station, just on the crossing between the main corridor and the metropolitan ring. Along the main corridor all kind of commerce is located: from specialized and traditional ones -like parts for sewing machines-, to fast-food chains and huge stores for construction materials. More than a half of the houses are consolidated, less than a quarter are multi-storey buildings, and the rest consist of houses in consolidation.

c) The area close to the City Hall. This area was occupied around the late 1960s. It has a regular spatial structure, with a clear hierarchy of streets and space left for public facilities. Spatially and functionally, the City Hall has influenced without doubt the land use and the consequent social arrangement of the area. Close to the City Hall, banks, furniture stores, restaurants, stores for office material and the like have appeared. Spontaneous centers have appeared not just in front of the City Hall, but also in the back: linear commercial centers which join together the Neighborhoods through an imaginary line. This intensive commercialization reflects in the morphology of the area: more than a half of the buildings are consolidated with approximately a quarter of them multi-storeyed; the rest is composed of buildings in process of consolidation.

d) An area that is located far from the Metropolis and belongs to both the oldest and to the youngest areas. Its spatial structure is neither regular nor the distribution of spaces left for public facilities; these distribute apparently by random and the spatial arrangement of the streets run parallel to the rest of the city, but these streets have no clear hierarchy in comparison to the other areas. In opposite to other areas, the buildings here at a first glance are not too old, and still the less consolidated houses are not deteriorated nor seem to be stagnated in the middle of the informal building process: more or less a half of the buildings are still in process of consolidation, while the rest consist of consolidated and multi-storey buildings. Curiously, commerce has not developed here as intensively as in the rest of the city. There is just a commercial strip in the main avenue and the concentration of banks and commerce is not the rule.

On the opposite end, the Young Settlements Area is mostly comprised of *Low Consolidated Blocks* with the following characteristics:

e) This area has a regular spatial structure with well distributed space for public facilities. It was occupied around 1980 but since then the living conditions have not improved much. This area is particularly isolated from the city of Nezahualcóyotl and from the Metropolis because this area limits with the rest of the lake to the north and it limits to the west with the metropolitan ring, which was built at a topographical altitude over the roofs of the houses. All this conditions have made of this place practically a cul-de-sac. Due to a relative low density, the speed of urban consolidation (drinking water and energy supply, drainage construction) was very slow and the area did not developed commercially, perhaps as a consequence of the same spatial isolation. Morphologically almost three quarters of houses are still in consolidation and there is a low amount of consolidated houses (more or less a quarter).

f) This area is also a young one, occupied around the 1980s. It has a regular spatial structure and the spatial distribution of public facilities is different to the other areas, in size, number and form of space for public facilities. Due to its relative low density, the urban consolidation, like the previous area, was slow. Considering the types of buildings, around three quarters of them are still in process of being consolidated and just a quarter consists of consolidated houses. Multi storey buildings here are seldom and that reflects in the almost absence of commerce. The social and spatial qualities of this area are mixed but in average the “indicators” for physical consolidation of the houses are predominantly low: in some parts of this area half of the houses have no drinking water into the house and the percentage of “cuartos redondos” or “one room dwelling” reach almost a fifth of the total. The structure of the population is either not homogeneous but it is composed of predominantly young families.

The rest of the City, the orange cluster, is a “buffer zone” which is composed of Semi Consolidated Blocks:

g) The area was occupied mostly at the end of the 1960s. The spatial structure is regular and the spaces for public facilities are homogeneously distributed. Thanks to a high density and the fact that the majority of the neighborhoods were included into a legalization program initiated in 1973, the urban consolidation process in this area was relatively fast. In 1970 the whole area was included into the sewage system network of the city and by the same year this area was supplied with energy. Ten years later, the number of paved streets here exceeded by far that of the younger areas. In this area no buildings for administrative purposes was built like the City Hall or similar, and the commercial corridors exist, but not as saturated as in the other areas. According to the typology used in this work, approximately half of the total houses have reached a consolidation level; just a few of the buildings are saturated, and the rest of the buildings, -almost the other half- are in process of consolidation.

Conclusions

The results allow us to conclude, that the morphological stage of “equilibrium” or “consolidation” may be a useful principle to identify some clues for the heterogeneity of the

social structure within informally developed settlements. The potential of the method developed in this work is nevertheless limited to the Ciudad Nezahualcóyotl case study. To research an eventual generalization of the method other settlements should be naturally considered. Each settlement has an own history and very specific local conditions. However, for the method exposed there are some variable conditions which could be considered in further detail.

Natural and topographical conditions influence without doubt the physical form of informal settlements. An informal settlement at a hill or at the coast will develop in form and constructive conditions very different from those developed at a plain terrain or in a city located thousand meters above sea level, for example the city of Mexico.

Another factor is the size and the form of the plot. How large or how small the plot is, will have a direct influence on the possibilities of internal development of the house as well as the proportion of the sizes of the plot.

The age of the settlement will influence also not just the changes in the house but also the land use of the building. Population in young settlement have needs which differ strongly from the needs of population in old settlements. The building thus may become a vertical commercial building, informal renting apartment, or it may remain with a residential use with the corresponding morphological typology.

In conjunction with the factors mentioned above, the location of the settlement into the city and induced planning measures will have also a direct influence on the way and the speed in which a settlement change.

With the latter, we may confirm the idea that urban morphology goes beyond giving answers to the logic of the built environment patterns, and may also provide us with powerful tools to decide and prioritize public upgrading actions.

Abstract. *This paper discusses the role of the urban form for the positive dissemination processes inherent to urban phenomenon. Positive dissemination means the interrelation of urban elements/factors, so that an action is analysed according to its propagation effects, resulting in a continuous transformation over the urban system, with impact on its regeneration. Certain places, public spaces or buildings, by their syntactic, typological and/or functional features, have the capacity to trigger such processes. Throughout a diachronic study of Évora (Portugal) urban form, under the Space Syntax perspective, configurational changes were identified and interpreted as the reflex or origin of new urban dynamics which contribute to urban dissemination processes. The results and corresponding discussion enabled the creation of a conceptual and methodological framework to categorize the selected cases, aiming at the distinction between positive and negative dissemination focus, as well the differentiation of their morphological, functional and resilience characteristics. By integrating a wider research that aims the creation of an urban regeneration strategic model boosted by positive dissemination processes, this study intends to contribute to the understanding of such processes when directly dependent from the case type.*

Key Words: *Positive dissemination, urban regeneration, systemic perspective, urban morphology; Évora (Portugal).*

Introduction

Under sustainability and urban regeneration perspective, urban projects, surgical interventions or tactical actions in the city promote global and long-term changes. Such results support the assumption that city interventions trigger changes in urban dynamics and promote a prosperity atmosphere that radiates into the system, expressing “positive dissemination processes”. This idea means the interrelation of urban elements/factors which enables the effects propagation of a particular action, resulting in a continuous transformation over the urban system, with impact on its regeneration. It is assumed that certain places, public spaces or buildings, by their syntactical, typological, functional and/or resilience features, have the capacity to trigger such processes.

This paper explores the positive dissemination processes inherent to urban phenomenon, supported by the study of cases in Évora (Portugal), selected according to a diachronic study of the city form under the Space Syntax perspective (The Theory of the Social Logic of Space). Throughout this investigation changes were identified and interpreted as the reflex or the origin of new urban dynamics which contribute to positive dissemination processes. Considering that the effect propagation in the urban fabric is related to its ability to be more or less permeable to such process, syntactic descriptions about that urban fabric accessibility are explored as tools with the potential to promote the comprehension of positive dissemination processes.

Because the main purpose of this research is to understand such processes when directly dependent from the case type, it is intended to develop a conceptual and methodological framework to categorize the selected cases. Besides that, it is aimed to distinguish between

positive and negative urban dissemination focus, as well to differentiate their morphological, functional and resilience characteristics. The methodological approach implied the research and critical reflection of urban form theoretical references.

This study is part of a wider research that seeks to set cross parameters to validate and evaluate the positive dissemination phenomenon able to inform and support a city intervention model, oriented to its regeneration and sustainability. The subsidiary premise establishes that because positive dissemination processes has the ability to magnify the effects of implemented actions, their comprehension will help to achieve improvements in the environment, maximizing resources and reducing investment.

Methodology

The methodological approach has a first phase based on the results of a previous morphological study about Évora (Gonçalves *et al*, 2013a), under the perspective of Space Syntax (Hillier and Hanson, 1984), by which positive dissemination focus were identified. The syntactic analysis enables to study the arrangement and interrelationship of space systems elements, by assuming that there is a social logic underlying the built space layout, and describing it by topological features among these elements. Configurational issues also reveal functional and social aspects inherent to the urban system throughout the “potential of movement”. Movement here is analyzed as an indicator of the relational aspect in urban space, translating how the space configuration interferes (and suffers interference) in the city flows distribution (Medeiros, 2006), assuming a leading role in the impact evaluation of urban changes. The previous study included the construction of axial and segments maps, in order to model pedestrian movement for different periods of the city's growth. The axial map consists of a representation containing all possible routes within an urban fabric, based on its simplification by tracing the fewest set of the longest lines. The lines position and interrelation in the system allows the calculation of different syntactic measures. The segments map comes from the axial map, in which the lines are divided between intersections, allowing a more accurate prediction of the movement pattern because are considered the direction changes, or continuities, important factor to the distance perception and routes choice (Turner, 2009). The maps show a gray scale that measures the variable level at each axis/segment, being the darker tones the higher levels and the lighter tones the lowest ones (Figure1, 2, 3 and 4). The syntactic analysis allowed the identification of centralities – high level of potential movement – and segregated areas, contributing to select positive dissemination focus.

The second phase focused on the construction of a conceptual and methodological framework to categorize the selected cases, aiming at the distinction between the urban dissemination focus which carry positive and negative effects, as well the differentiation of their morphological, functional and resilience characteristics, i.e., an urban system capacity to incorporate change without losing its features (Walker and Salt, 2006). The proposed categorization framework is grounded by the syntactic analysis, positive dissemination cases/focus and theoretical references concerned with the urban elements classification.

Finally, at the third phase, through the results discussion, it is expected to achieve a sustained contribution to the understanding of positive dissemination processes and corresponding performances when directly dependent from each case features.

Évora urban dissemination focus

Interpreting a syntactic analysis

Évora city, located in Portugal inland, is characterized by its confined delimitation that grew by its attraction power over the surrounding regions. The settlement presents deep differences

between its parts: the historical zone (the inside-walls classified area), the consolidated area (walls adjacent areas) and the emerging city (formed by the territory discontinuous filling).

The syntactic study of Évora urban form evolution looked into the existing positive dissemination processes (Gonçalves *et al*, 2013a). Interpreting the morphological diachronic changes, it was assumed that the urban expansion and transformation can contain itself urban dissemination processes. It was also possible to evaluate and measure the potential movement patterns in the urban system using the Integration and Choice variables. Integration deals with the system accessibility. The most integrated axes are the most permeable, accessible and, probabilistically, the most used according the configuration role. It means that the most integrated axes will have a greater ability to create movement, which is crucial to urban dynamics, constituting a potential centrality and assuming a leading role to the attraction of movement flows and diversity of uses. Thus, Global Integration and Local Integration reveal, respectively, global and local potential centralities in the system. Moreover, Global and Local Choice indicate the most used segments in the global and local routes in the system, respectively.

The maps comparative study and corresponding correlations with the attractive characteristics of some urban stretches, under Whyte (1980) perspective, allowed the deduction of uses distribution and the most attractive areas with an effective ability to influence and contaminate positively the surrounding environment. Urban areas, public spaces and buildings of great attractiveness were identified by their physical and visual qualitative characteristics and by their configurational features. These ones correspond to high levels of accessibility and use, and leads to a non-conscious appropriation by individuals and a form of behaviour compatible with the potential movement pattern (Hillier *et al*, 1993). A more accessible and permeable space tends to be more used ending as a meeting, passage and usufruct place, easily subjected to transformations throughout social interactions which gradually disseminate the corresponding effects from space to space.

On the other hand, less accessible and segregated areas were also identified, corresponding to places with a tendency to be less used and with reduced functional and social diversity. These ones, when associated with marginal uses, insecurity and physical degradation may be classified as negative dissemination focus. Although these cases are not the study object, they are defined by opposition to the positive dissemination focus helping to consolidate their understanding.

Syntactical analysis reveals, through the Global Integration values, that “Ringstrasse” around the city walls (n.14) is the centrality of Évora urban system (Figure 1). By its strategic position in the urban fabric, attracts and articulates several functions: Polis (n.40), the city walls urban regeneration program, Horta da Porta Neighbourhood (n.33), Remédios Monastery (n.43), Bullring/Multipurpose pavilion (n.9), Epral school (n.34), Espírito Santo Hospital (n.24), Patrocínio Hospital (n.25), Public Garden (n.26), Rossio de São Brás Square (n.11), Cafe (n.23), Gabriel Pereira school (n.4) and Pingo Doce supermarket (n.17).

Syntactic study of Évora’s evolution (Gonçalves *et al*, 2013a) revealed that, in earlier times, the most integrated axes were coincident with those of Evoracom (n.7 – Figure 2), currently the most used paths for the journeys within the intramural city. Evoracom was an urban regeneration program implemented on historical streets and commercial buildings, and included interventions at Giraldo Square (n.12), Avis Square (n.13) and Porta de Moura Square (n.22). The position of Giraldo Square in the urban fabric works as an attraction point, recruiting the city users, and as a distribution node. The paths that depart from here towards city gates have a high use too, creating urban dynamics that affect the buildings nearby, e.g., residential buildings (n.1) and institutional, services or commercial buildings subject to conservation and/or rehabilitation actions. The Sepúlveda Palace (M’ar De Ar hotel unit - n.2), S. Domingos complex (n.6) and Garcia de Resende theater (n.42) are located in synergy with the path towards Porta da Lagoa (a city gate). Towards Rossio de São Brás square (another city gate), is located the Municipal Market (n.30), Verney College (n.36) and D. Manuel Palace (n.21).

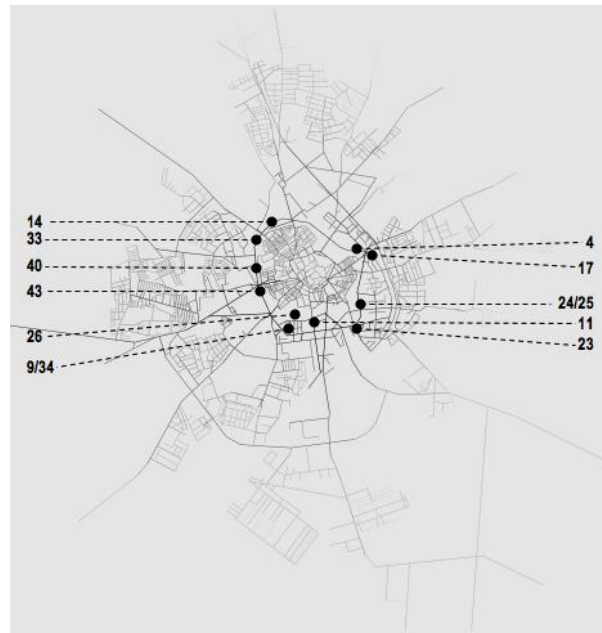

Figure 1. Syntactic analysis (axial) – Global Integration (2013).

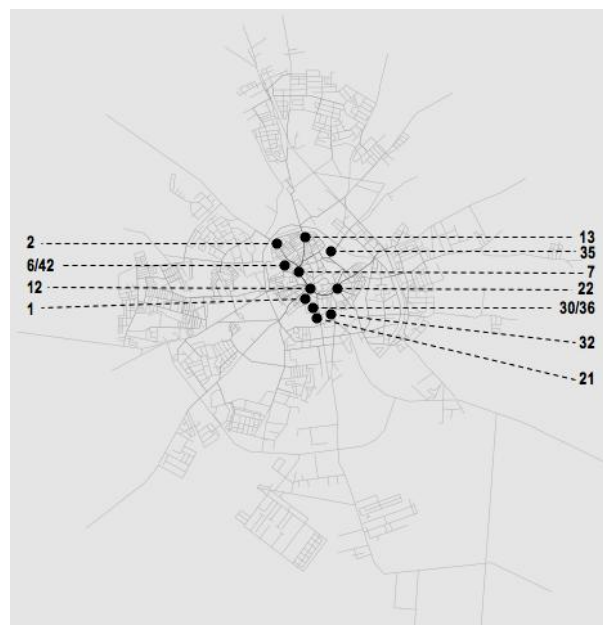

Figure 2. Syntactic analysis (segments) – Local Choice - R1200m (2013).

Near some of these high use routes are located the Eborim shopping centre (n.32) and Cerca de Santa Mónica private condominium (n.35). Although their privileged positions in the urban fabric, were selected for being classified as negative dissemination focus. Eborim shopping centre is now closed and going through a process of physical degradation. If working, it could be an attractor in the city. Cerca de Santa Mónica, because it is a private condominium, promotes spatial and social processes of segregation, with no relation with the surroundings (Ribeiro, 2012).

The maps and syntactic measures reveals that Roman core (n.15) is spatially segregated (Figure 3). However, it is a place of great influx of people, especially tourists. This is due, firstly, to the fact that the zone is bounded by the memories of the Cerca Velha (first city walls), the first ringstrasse, which have a high potential of movement. Secondly, because there are located monuments of great historical value, e.g., the roman temple (its surroundings integrates the urban regeneration program Acropole XXI - n.44), the Cathedral (n.19) and the roman baths inside the City Council building (n.20).

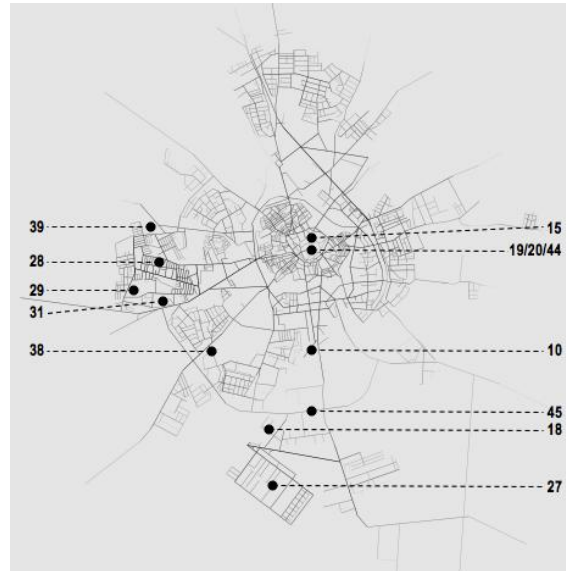

Figure 3. Syntactic analysis (axial) – Local Integration - R5 (2013).

The city expansion outside the walls consolidated some local centralities (Figure 3), the first of which, between Rossio de S. Brás Square and the Train Station (n.10).

Another local centrality is the industrial zone where are located the Évora Industrial and Technological Park (n.27), Intermarché supermarket (n.18) and Almerim industrial area (n.45).

Malagueira (n.28), Santa Maria and Alto dos Cucos residential neighbourhoods constitute another local centrality which attracts other uses, e.g., the Maintenance Lane (n.29), a precinct for the sport activities. Nearby these neighbourhoods are located the Municipal Swimming Pools (n.39). At the south of this area, but with accessibility low levels, therefore more segregated, is located the Cruz da Picada social neighbourhood (n.31). This case is considered a negative dissemination focus, because it has a negative connotation due to insecurity feeling and some physical degradation.

Ecopista (n.8 - Figure 4), a pedestrian and cycling pathway resulting from a recycled railroad, is also contributing to new local centralities formation, the north residential areas. Ecopista articulates spatial heterogeneities (Gonçalves *et al*, 2013b) and presents itself as a constant choice in the daily routes. Adjacent to Ecopista is the old “Leões” Factory (n.3), built in a direct relationship with the railroad. The old factory is now the Architecture School and keeps the connection with the new Ecopista – the preferential pedestrian access.

The Turgela stream (n.38), despite the syntactic values below average, like the Ecopista case, introduced configurational changes to the urban fabric. What previously constituted a barrier became permeable and generated a new movement pattern and consequently new urban dynamics (Figure 3).

The Global Choice variable analysis (Figure 4) enables to conclude that, outside the walls the routes that come from the city gates are the most used. At the pathways that come from Raimundo gate articulated with the southern variant road (the third city ring road) are located

distinct functions, e.g., Bus Central Station (n.41), Severim de Faria school (n.5), Horta das Figueiras commercial area (n.37) and Continente supermarket (n.16).

Figure 4. Syntactic analysis (segments) – Global Choice (2013).

The conclusions of configurational study by syntactic analysis demonstrate that accessibility is an important factor to conform local or global centralities (and usage densities). This study is also an instrument for the selection of positive dissemination focus (and negative – cases n.31, n.32 and n.35) in Évora which are to be evaluated and classified (Table 1).

The proposed classification system seeks to answer to specific purposes of the research and it's not supposed to be a single taxonomy of physical, formal and functional urban elements. In this context, and always considering the selected cases, use was made of the analysis and reflection of relevant theoretical references to support the proposed classification system.

Urban dissemination effect classification

The study focuses on positive dissemination cases, which are places, public spaces or buildings, that generates and attracts movement, promotes social interaction and are useful and profitable for the urban system. Are identified by the positive influence on the urban surroundings at multi dimensions: environmental (built environment regeneration, accessibility, diversity of uses), social (diversity, influx of people) and economical (trade, diversity of activities). In turn, negative dissemination focus are the place, public space or building, devalued and counterproductive in the urban system, that promotes movement dispersion and dissuasion of social interactions. In contrast, are identified by its uninhabited and devoid content at multi dimensions: environmental (degradation of the built environment, poor accessibility, lack of uses), social (absence of people or affluence of problematic and delinquent groups, insecurity feeling) and economical (lack of activities and no trade).

Morphological classification

The morphological approach aims to study the settlements through their urban fabric configuration, its volumetric characteristics, land use and subdivision, including configurational changes observed over time, focusing the growth and transformation patterns and processes (Heitor, 2001; Carmona, 2003).

Urban form studies have specificities that enable the identification of distinct approaches: historical, historical-geographical, descriptive and normative approaches, this last one through mathematical techniques, in which Space Syntax fits (Heitor, 2001). With reference to Rossi (1966), Conzen (Whitehand, 2001), Lynch (1960), Krier (1975), Kostof (1992) and Carmona (2003) studies, articulated with the syntactical analysis results and facing the selected cases/focus, morphological categories proposed are arranged by scale, type and form (Table 2).

Table 1. Urban Dissemination Focus

	Designation	Location		
		Historical City	Consolidated City	Peripheral City
1	Housing Rehabilitation at Historical Centre	x		
2	Sepúlveda Palace/M'ar De AR Hotel	x

Table 2. Morphological categorization

Category	Definition	Cases
Scale		
Urban Area	Group of built elements and public spaces, in an area more or less bounded physically, of similar properties, continuity and spatial features, formal and/or typological homogeneity, to which is associated a common vision (Lynch,1960; Rossi,1966).	7;15;27;28;31;33;37;44;
Public Space	Includes all open spaces, all kinds of spaces between buildings (Krier,1975) and open access spaces, regardless of their shape and/or function.	8;11;12;13;14;22;26;29;38;40.
Built Structure	Buildings or physical structures, urban phenomenon element, which implementation, aggregation and/or alignment conforms the system of open/public spaces.	1;2;3;4;5;6;9;10;16;17;18;19;20;21;23;24;25;30;32;34;35;36;39;41;42;43.
Type		
Morphological Unit	Group of streets, plots and/or buildings, which presents uniformity regarding its formal characteristics that distinguish it from the surrounding areas (Heitor,2001; Whitehand,2001).	6;7;15;27;28;31;33;35;37;44;45.
Path	Public space of linear features which constitute circulation channels. The paths are the elements by which the whole can be organized (Lynch,1960).	8;14;40.
Node	City strategic location, constituting a confluence place, focus of attractiveness and movement distribution (Lynch,1960).	11;12;13;22.
Precinct	Open space, with public access, but bounded by physical barriers such as walls or hedges, may having or not restricted timetable.	26;29.
Autonomous Element	Isolated/independent building or physical structure. Sometimes are elements of singular characteristics that distinguish it from the others and works as a landmark (Lynch,1960). Are autonomous elements, buildings surrounded by open space and monumental structures that stand out and enable an autonomous reading, even when physically connected to other buildings.	2;3;4;5;9;10;16;17;18;19;21;24;25;30;32;36;38;39;41;42;43.
Dependent Element	Building or physical structure aggregated to other buildings, part of a group or a facade, with no autonomous reading.	1;20;23;34.
Form		
Regular	Space, place or urban structure with linear features or pure geometric forms, understood as the ideal shape (Carmona,2003).	
Irregular	Irregular, natural or organic shapes, corresponding to spaces, places or urban structures implemented according to the urban fabric availability which arises throughout its history and by an improvised process (Kostof,1992). Not corresponding to any pure geometric form, seem generated by a natural and non conscious process, based on pedestrian movement and influenced by the topography (Carmona, 2003).	
Loose	Space, place, or built structure, not closed or physically constrained, with flexibility characteristics and formal adaptability (Carmona,2003). According to Peña (1987) flexibility can be assessed under extensibility, convertibility and versatility criteria.	
Tight	Space, place, or built structure, physically constrained, or controlled, rigid and inflexible (Carmona,2003).	

Functional classification

The study of urban form is not indifferent to the functional dimension. The literature review showed that functional classifications proposed by many authors rarely are dissociated from the spatial form. According to Kostof (1992) an exclusively formal approach has limitations. The functional dimension is about how the spaces work, i.e., how the environment supports the uses (Carmona, 2003).

Syntactic analysis reveals a hierarchy of movement established by the urban fabric configuration, defining areas of greater or lesser concentration of flows. The areas of greater concentration of movement tend to be more attractive and to draw uses and functions that take benefit from this movement (Medeiros, 2006). Though, it is believed that positive dissemination processes are not exclusive of configuration features, movement patterns and densities, i.e., can be generated and boosted by attractiveness features of certain uses and activities. So attractive uses have the ability to attract and to create new and more movement flows which can promote changes in the spatial configuration (Medeiros, 2006), and have the ability to trigger and boost positive dissemination processes. Thus the functional attractiveness refers to the space occupation when determined by the attractiveness power of a function or activity inherent to that space, regardless its morphological characteristics (Ünlü, 2009).

In view of theoretical considerations of Lynch (1960), Rossi (1966), Krier (1975), Kostof (1992), Carmona (2003), Brandão (2008), Ünlü (2009) and Gehl (2010), and the selected cases/focus, the proposed functional categorization considers two levels: the first related to diversity and, the second, related to specific functions that each case/focus can include (Table 3).

Resilience classification

The resilience concept is a sustainability key attribute. In the urban phenomenon context resilience is associated to the idea of durability, maximization of resources, requalification of problematic areas and urban regeneration. In this matter resilience is an important condition for the urban system elements. Though, facing negative dissemination focus, the system resilience is not a desirable condition because it can put the system in a situation of persistence even when interventions are implemented aiming the change towards a positive dissemination process. Vulnerability in such cases is an advantage because it works as a facilitator of a transformability process to reverse the negative and counterproductive situation.

Urban system resilience or vulnerability is related to its basic morphology and infrastructures that support its growth and dynamics. Experience suggests that urban areas with higher permeability, mixed uses, diversity of buildings and shared public spaces, tend to have greater ability to accommodate change (Carmona, 2003).

In view of these considerations each case/focus is classified, firstly, as resilient or vulnerable, secondly, as robust, diverse and/or accessible (Table 4).

Results and discussion

This study led to the definition of a conceptual and methodological strategy to categorize positive dissemination focus in Évora (Figure 5). The strategy requires, firstly, the translation of the syntactic analysis results, secondly, its correlation with the discussed theoretical references and with the observed phenomena *in situ*.

The syntactic analysis, through graphical and quantitative tools, enabled the study of urban fabric configuration and revealed characteristics such as centrality, continuity, segregation, confluence or dispersion points. The study allowed the classification of positive (and negative) dissemination focus, contributing also to their morphological classification. The resulting movement pattern denounces the most accessible places and, consequently, the areas with an higher probability to be attractive for users and activities and to be places of diversity, with

implications for the functional classification. The most accessible places tend to present a greater ability to incorporate changes and new uses, a relevant factor for the resilience classification.

Table 3. Functional categorization.

Category	Definition	Cases
Functional Diversity		
Multifunctional	Space, place or building in which different activities take place simultaneously. Are also considered multifunctional the spaces that, because of its flexibility characteristics, support several uses, planned or not, at different times (Carmona,2003).	6;7;8;9;11; 12;13;14;15; 20;26;33;38; 40;44.
Monofunctional	Space, place or building for a single use. The monofunctional spaces tend to be physically constrained or controlled spaces (Carmona,2003). Includes industrial areas and residential neighbourhoods, even when there are some local services and activities of proximity.	1;2;3;4;5;10; 16;17;18;19; 21;23;24;25; 27;28;29;30; 31;34;35;36; 37;39;41;42; 43;45.
Function		
Movement	Space or urban structure for car and/or pedestrian flows, i.e., for circulation function. The pedestrian movement also contains cultural, social and economic functions (Carmona,2003). Movement corresponds to a necessary function which occurs regardless the exterior conditions and the physical environment quality (Gehl,2010). According to Rossi (1966) movement is one of the key functions of the city. This category also includes "travel spaces" as stations, interfaces and parking (Brandão,2008).	7;8;10;11;12; 13;14;22;38; 40;41.
Social	Space or urban structure where activities that depend on the people affluence and interaction occur, e.g., festive events, games, kiosks and cafes (Brandão,2008; Ünlü,2009; Gehl,2010).	6;7;8;11;12;13; 15;23;26;33; 38.
Economic	Space or urban structure where people and activities affluence correspond to economic flows, by goods or services trade. The economic function comes also associated with industrial areas intended to confer economical benefits to the city.	2;6;7;9;11; 12;13;15;16; 17;18;22;27; 30;33;37;45.
Institutional	Space or urban structure that works as public or institutional equipment and seeks to meet the needs of the population, e.g., health, education and culture. Includes hospitals, schools and cultural equipments. Act as catalysts due to their contribution to urban dynamics (Rossi, 1966).	3;4;5;20;21; 24;25;34;36; 39;42;43;44.
Residential	Built element, neighbourhood or building, with residential characteristics, satisfying a city major function (Rossi,1966).	1;6;28;31;33; 35.
Leisure	Space or urban structure where occur activities related to the contact with the nature and landscape contemplation or related to cultural, memorial, historical, and symbolic function. Includes a functional dimension of aesthetic and/or visual nature. Correspond to optional activities carried out under favorable external conditions and/or attractive physical environments (Gehl,2010).	8;9;11;12;13; 15;19;20;21; 22;26;29;38; 39;40;42;43; 44.

Table 4. Resilience categorization.

Category		Definition	Cases
Resilience And Vulnerability			
Resilient Consolidated	And/Or	Spaces, places or buildings, with capacity to absorb disturbance and to undergo change, retaining essentially the same function, structure and feedback, i.e., systems capable to be subject to changes without crossing the threshold that puts the system in a new different regime (Walker and Salt,2006). Resilience depends on robustness, diversity and accessibility factors.	1;4;5;7;10;11; 12;13;14;15; 16;17;18;19; 22;23;24;25; 26;27;28;29; 30;31;32;33; 34;36;37;39; 41;42;44;45.
Vulnerable Object Of Intervention Cionado – New Life Cycle	And/Or	Spaces, places or buildings, vulnerable to disturbance and change acquiring a new function, structure and/or feedback, i.e., systems that cross a threshold towards a new distinct regime when subjected to certain changes (Walker and Salt,2006). Includes the cases with a new life cycle due to an intervention. Vulnerability depends on factors such as the lack of robustness and diversity. Accessibility is also a crucial issue for the space vulnerability.	2;3;6;8;9;20; 21;35;38;40;43.
Factors			
Robust		Space, place or building, with ability to accommodate change without significant changes to its physical form, often impregnated with value, meaning and/or symbolism, resisting to functional obsolescence (Carmona,2003). Robustness depends on adaptability and flexibility features, typical of loosen forms.	
Diverse		Space, place or building that supports different types and patterns of social and/or functional activity. Diversity strengthens the system resilience once it allows greater variety of responses, greater ability to absorb disturbances and greater flexibility (Walker and Salt,2006).	
Acessible		Space, place or building, with a permeable and central position in the system. Accessibility influences how the consequences of a change implemented in one part of the system are felt and answered by others, in terms of speed and firmness (Walker and Salt,2006). Accessibility levels, in this research are quantified by syntactic measures.	

The articulation between the proposed categorization system and the cases/focus indicate that their features have direct implications for the performance and dimension of the transformation processes experienced by the city. Urban areas and public spaces with high levels of accessibility and usage tend to be more efficient to trigger positive dissemination processes. Built structures, tends to be more permeable to such processes when triggered by surrounding public spaces. And attractive uses are a key factor to trigger these processes, once they have the ability to attract and to create new and more movement flows which can promote changes in the spatial configuration.

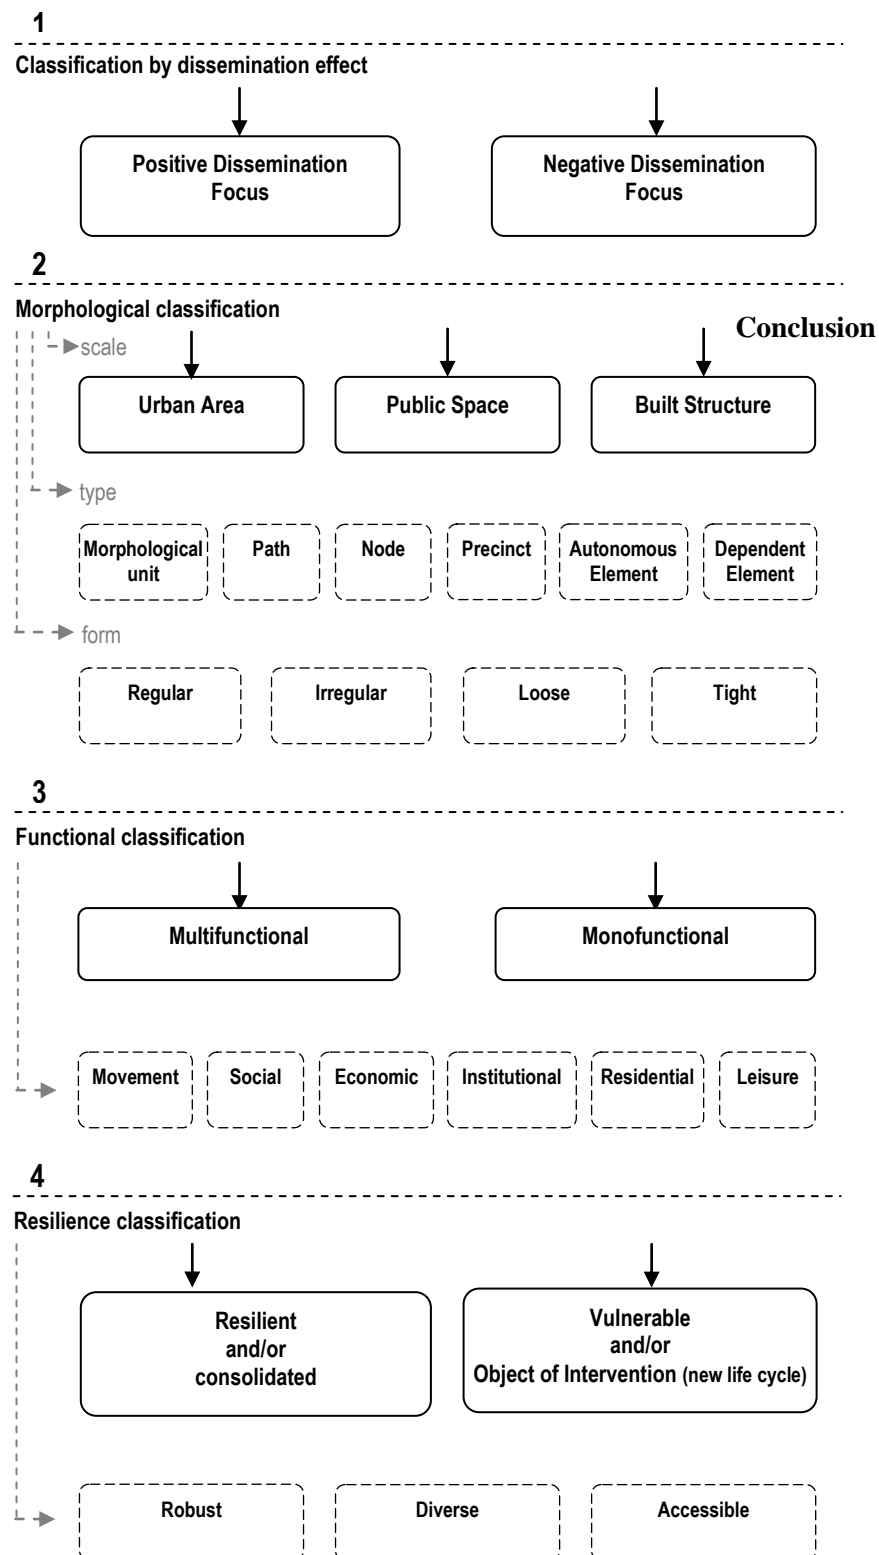

Figure 5. Categorization System.

Referring to positive dissemination focus in Évora which deals with the urban dynamics affecting the environment, this study searched the definition of morphological, functional and resilience categories. The aim was a contribution to the positive dissemination processes, and corresponding performances, understanding when directly dependent from the case characteristics. Once categorized the cases/focus, the future goal is a new selection, in the universe of positive dissemination focus, that were subject to intervention in the past and shows, today, transformations in the surroundings directly related to the intervention. Then it's intended to apply an evaluation and evolution model of positive dissemination processes and create past, present and future scenarios. Once confronted these scenarios and correlated with the categories inherent to each case, the objective is to achieve an accurate assessment of the transformation processes performance in the city. Through this approach, it will be possible to construct a theoretical framework, illustrated and sustained by the study of cases in Évora. The final aim is to develop and validate a generator model of urban regeneration strategies boosted by positive dissemination processes believing that these processes are natural facilitators of the urban system sustainability.

The sociability of the street interface - revisiting West Village, Manhattan

Garyfalia Palaiologou, Laura Vaughan

London, NW1 2BX. E-mail: g.palaiologou@ucl.ac.uk, l.vaughan@ucl.ac.uk

Abstract. *This paper examines the micromorphology of street interfaces, considering how street life is shaped by the emergent pattern of built form and spatial layout. In an effort to reassess Jane Jacobs's conception of liveability, the study uses urban form and space syntax methods to record the changing micro socio-spatial texture of West Village, Manhattan. The paper discusses the way in which pedestrian experience varies and changes as the characteristics of street facades change: from the postmodern solid block front to an alignment of short row house facades or from a wholly domestic setting, to a street lined with shops and businesses. In order to understand the urban streetscape as a place of social activity, the study examines the built volume in terms of building-street connections aggregated within a block frontage. The resulting pattern is analysed to consider how morphological properties might give rise to street interaction. The study also maps the mixture of buildings by age and relates this pattern to the spatial distribution of non-domestic land uses, the street network configuration and associated urban interfaces. Conclusions suggest morphological features of the built form which are more likely to generate and support a vibrant street-life over time.*

Key Words: *Micromorphology, urban interfaces, Jacobs, West Village, row house.*

Introduction

The field of urban morphology has fundamentally contributed in a morphological reading of the built environment identifying the basic components of urban form: the building, the plot and the street (Conzen, 1960; Caniggia and Maffei, 1979; Korf, 1996; Çalışkan and Marshall, 2011). One of the main inquiries of morphological studies refers to the organisational rules of the way building units are aggregated to consist urban space. Space syntax studies on the other hand, aim to shed light on the social output of spatial patterns, to interpret 'the social logic of space' (Hillier and Hanson, 1984). Combining principles and methodologies from both fields, this paper aims to examine the way the urban components work together (the building, the plot and the street) to configure varying spatial and in turn social situations in the street domain. The study focuses on the role of building-street connections in creating sociable places.

In one of the earliest publications of the subject, *The Social Logic of Space*, building-street interfaces are seen to shape social encounter. (p.143). Subsequent work by Julienne Hanson's (2000, 2009) identifies the potential role of building morphology, as an extension of urban interfaces¹², in creating sociable places. This street scale focus, lies within the wider context of the way in which cities are theorised in the field of space syntax, where the spatial and physical properties of urban space are seen as generators of movement patterns, which in turn shape patterns of potential co-presence and encounter, creating the 'virtual community' (Hillier 1989, p.13). The author suggests that space distributes the physical presence of users and thus organises the potential patterns of co-presence and encounter. Co-presence and encounters are thus two basic preconditions for social events to be generated within space. The aim of this

¹² In Hanson's words regarding non-lively streets: '... the whole story is one of a ruptured interface between dwelling and street' (2000, p.113). This relates to Jacobs's observations regarding the importance of 'eyes on the streets', namely of a building-street interface that allows for interaction between the users of the building and the street occupiers or moving pedestrians.

study is to build on this work by looking at the way varying types of interface bring about varying potentials for interaction. The analysis here focuses on a detailed analysis of how buildings aggregate along block faces, testing the hypothesis that building-street interface corresponds to the street's wider connections within the city's street network.

The discussion in this paper is based on mapped and quantitative data collected for the area of West Village in Manhattan, New York. Acknowledging academic critiques that seek for an evidence-based investigation regarding the validity of some of the mostly cited, yet empirical, urban design theories (extensively discussed in Marshall, 2012), this study revisits West Village to take a step towards reassessing Jane Jacobs's conception of *liveability* using quantitative data and a morphologically informed approach.

Furthermore, leaving aside theoretical motives, West Village is an interesting case in its own right due to its particular built form properties. Restrained by the physical limits of a fixed geographical area, urbanisation processes in the Manhattan Island have been continuously challenging the building volume, building densities and the potentials for a vertical expansion of the city. However, West Village stands out as a special case within the Manhattan metropolis. Since 1969, Historic District Designations have protected the historic building stock of West Village. The surviving row houses in the Village are not just reminiscent of the neighbourhood's picturesque qualities; instead they are living carriers of the past and the present. Being used, altered and re-used over time to house shifting densities, uses and lifestyles, the historic built form works as an incubator for street liveability. At the same time, the non-historic parts of the area, lying at the urban blocks of the west waterfront, have faced far more extensive transformations which included block-scale demolitions and redevelopments as well as gentrification projects. As a result, the present state of the Village streetscape brings together varying morphological urban settings; from row houses and tenements, to post-modern blocks and former industrial buildings. In this respect, West Village consists a rather interesting case study where we can explore and compare the levels of social activity that varying morphological settings appear to support and develop over time.

In what follows, the discussion introduces briefly the role of citywide urban forces in shaping the spatial and physical context in West Village historically. Then, the properties of the historic built form in terms of the building-street interface are described. Following this, the current Village streetscape is analysed in terms of the social encounters organised by the built form. In particular, the study looks at the properties of the street interface in historic and non-historic parts of the case study area. Finally, the paper discusses the role of the street network in configuring varying street profiles.

West Village

With its street gridiron dating back to 1790 (almost 20 years earlier than the Commissioners' Plan of 1807-11), West Village is considered one of the oldest parts of Manhattan. Located in proximity to the financial district and downtown city centre, the Village was challenged by the pressures of urbanisation as early as 1830s (Ware, 1965, p.9). In its early development the area was building up a profile as a desirable neighbourhood for the wealthier parts of the population, which soon attracted an extensive spread of row housing. At the same time the piers and transport depots were forming the industrial west waterfront. This strong functional split – and correspondingly, morphological split in terms of the built form – has since played a definitive role in the history and development of these two contrasting districts: the Village heart, later to become part of the Historic District Designation, and the west waterfront which has faced large scale demolitions and redevelopments.

From the earliest period onwards, the varying socio-economic forces of the spreading urbanity started to shape the diverse architectural profiles of the neighbourhood (Dolkart, 2009:115-116). Figure 1 summarises the contrasting urban forces which were challenging West Village at the turn of twentieth century. Most of the row houses were gradually converting into

multiple-occupancy, if managing to escape demolition by giving way to tenements, apartment buildings and small industrial units¹³. Building development varied in order to accommodate the needs of shifting populations, functions and economic standards. The row houses (both new and existing) were converted into work-live units¹⁴ or apartments for single living. Tenement building spread around the area to house manual labourers, creating challenging densities, high lot coverage and consequently leading to poor living conditions. High-rise apartment buildings with commercial ground floors filled up the north-south citywide street alignments, such as Sixth and Seventh Avenues. And finally, warehouses and small manufacturing units to support industrial uses were constructed on the western Village blocks close to the piers. The profile of the neighbourhood changed even further with the extension of Seventh Avenue in 1914 and Sixth in 1918. These street extensions increased the area's centrality within the Manhattan grid and turned the Village into more of a passage, rather than just a self-contained area. Figure 2 shows space syntax analysis of the Manhattan street network before and after the street extensions (darkest colours represent higher values in accessibility and permeability¹⁵), illustrating the sudden increase in the area's significance within the city network. During the second half of the twentieth century, the physical unity of the neighbourhood underwent dramatic transformations, some of which had a significant impact on the social image of the streets. An example of such redevelopment was the demolition of all buildings in the block bounded by Barrow, Morton and Washington Streets to be replaced with post-modern housing (construction started in 1969 and completed in 1974).

Notwithstanding all these pressures, a significant number of row houses survived in the area¹⁶. Protected by the Historic District Designation in 1969, the row houses in the heart of the village are today intermingled with younger buildings, creating vibrant street qualities of functional and morphological mixture. Mapping the features of the West Village streetscape in the present times (c.2011-2013) and comparing the historic and non-historic parts, the following analytical parts of the paper aims to address properties of the built form that have a potential impact on street liveability. The role of the street network in shaping a street's social profile is also discussed.

The historic building-street interface

Before looking at the urban streetscape in the Village as a whole, it is important to look solely at the historic building typologies that this study takes into account and to discuss some of their morphological properties. More particularly, the study considers the row house and tenement building types (Figure 3). Descendants of the row house typology (Davis, 2006:151-153), tenement buildings can be divided into two further typological groups: the 'old-law' tenements (including the 'railroad' and 'dumb-bell' types) and the 'new-law tenements' (Plunz, 1990:13, 49). Old-law tenements are five- to six-stories high and cover up to 90 percent of a typical 25-by-100-foot Manhattan lot (coverage reduced to 80 percent after the Tenement House Act of 1879). Living conditions in these buildings were characterised by severe lack of light and ventilation. Slightly improved - to match standard plans approved by the Tenement House Act of 1901 - the new-law tenements are taller buildings with a façade length almost twice the size

¹³ For instance, the construction of Union Terminal Freight Station and of U.S. Appraises Stores (c.1950-52) at the south-west blocks of the Village led altogether to around 140 building demolitions.

¹⁴ Work-live units refer to artists' houses and studios as well as to commercial-residential buildings.

¹⁵ Space syntax analysis calculated in Depthmap software (Turner, 2001). The measure of combined integration and choice at different scales of analysis represents the potential for a given street section to be used for movement through and around the area within that given distance.

¹⁶ For a discussion regarding the spatial and social factors that enabled the continuity of the historic row houses in West Village see the discussion in a previous ISUF conference paper: Palaiologou and Vaughan, 2012.

of row houses and old-law tenements. New-law tenements usually cover around 70 percent of a 40- or 50-by-100-foot lot (*ibid.*, p.47-49).

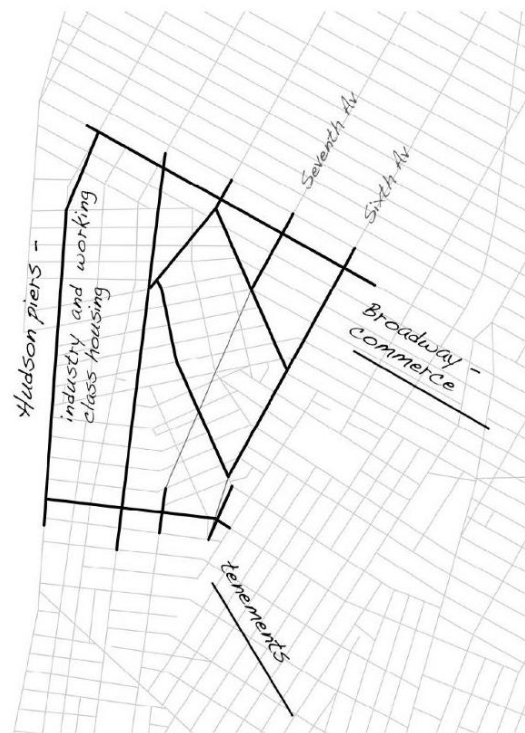

Figure 1. West Village - urban challenges at the turn of twentieth century.

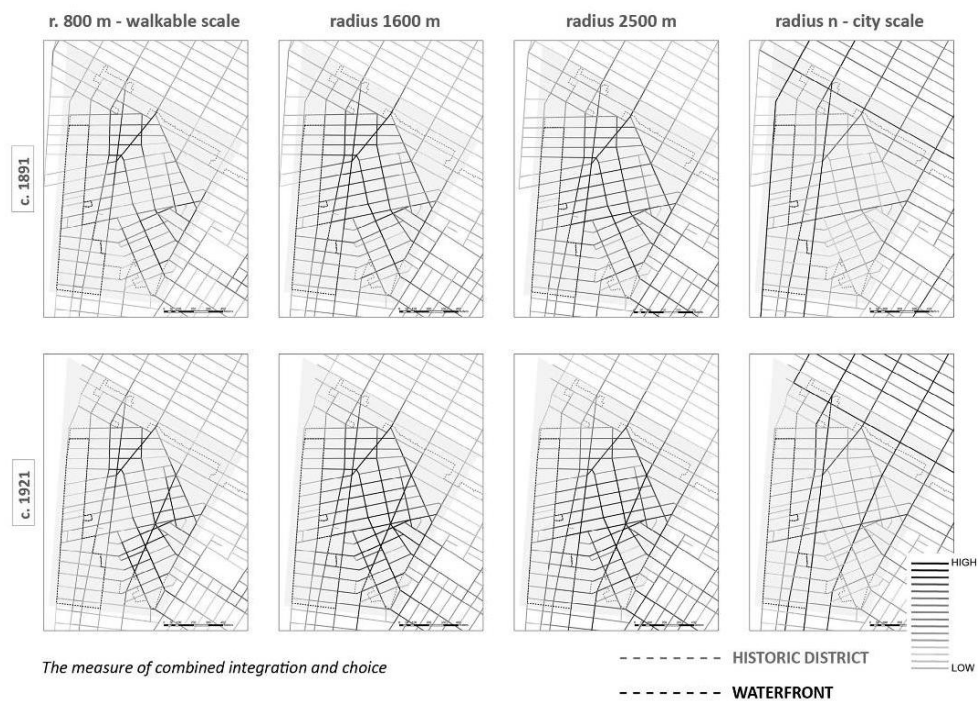

Figure 2. West Village - analysis of the street network properties before (c.1891) and after (c.1921) the extension of Sixth and Seventh Avenues.

Besides row houses and tenements, there are other historic buildings as well with long presence in West Village. Such buildings are small industrial units, factories, schools etc. However, the primary focus of this study is the façade organisation of row houses, and consequently, their building-street interface. For this purpose, the analysis here distinguishes between the row house and tenement typologies for two main reasons: on the one hand, these building types present regularities and typological consistencies in terms of the façade treatment. And on the other hand, row houses – and tenements as their descendants – represent the most common residential building type of the Commissioners' historic Manhattan.

Figure 4 illustrates a survey of the historic built form presence in West Village. The map shows the row houses and tenement buildings still existing in c.2013. The buildings' colour range (dark-oldest, light-youngest) represents four main typological groups: the shell of a single-family row house (black); the railroad and dumb-bell¹⁷ types of old-law tenements (dark grey); the new-law tenements (grey); and finally, the remaining buildings which do not belong to a particular building type and are mostly later developments. It is clear from the map that the Historic District Designations capture the majority of the historic rows and tenements within the study area.

More particularly regarding the façade organisation (Figure 3), in the early row houses the building frontage is characterised by a trilateral vertical alignment of casements. The domestic door entrance lies at either side and is usually accessed via the *stoop* (stepped entrances or porches). In the cases of an additional function occupying the ground floor – usually commercial – the non-domestic entrance is once again aligned under either the central vertical zone of windows or to one side. Accordingly, alignment with windows is also retained in the case of an additional separate domestic entrance when the single-family row house is turned into multi-dwellings. There are also examples where the second domestic entrance is placed underneath the elevated stoop of the main old entrance (like in the more grandiose Italianate style row houses). Due to the small scale of these buildings, façades present in most cases a maximum of two thresholds. The railroad and dumb-bell façades (old-law tenements) which are slightly bigger in scale (both for façade length and height) are organised in four columns of windows, with the main building entrance located in the middle of the façade length. Often, this building type presents additional commercial uses in the ground floor which are placed at the sides of the central domestic entrance. Finally, the new-law tenement typology, covering larger plots, introduces a more solid ground floor, with fewer openings to the street. In other words, the older narrower building types are found to present a denser pattern of building-street connections squeezing as many thresholds as possible into the façade.

Figure 3. West Village - row house, old- and new-law tenements.

¹⁷ Variations of the old-law tenement building type; for details see Plunz, 1990:13, 49.

Figure 4. West Village - row houses, old- and new-law tenements (c.2013).

The record of building thresholds collected from a survey of West Village conducted by the first author in 2011 confirms this last observation regarding façade length and density of thresholds (see Table 1). In order to form a general overview of the *density of thresholds* in the area of West Village for each one of these three historic building types as well as for the non-historic buildings, we can look at the ratio of the *total façade length* for each type to the *total number of building entrances* in each case. Based on the features of row houses in West Village (1325 row house units, 1469 sides facing streets), results show that in a streetscape completely built up with row houses a pedestrian would anticipate passing a building threshold approximately every 3.8 meters. A similar spacing between thresholds is expected in a hypothetical route constructed alongside old-law tenements (245 units were recorded and 272 façades), where a door would be expected every 4.1 meters. This slight deviation between the two building types is explained by the slight increase in plot size for the latter. A new-law tenement streetscape would be looser in terms of building-street connections, with doors lining up every 4.5 meters. In general, these historic building types commonly form a rather dense building-street interface. Summarising the previous results, the estimated frequency of thresholds for the historic built form is a doorway every 4 meters on average. In contrast, the analysis shows that the remaining buildings in West Village are likely to present an entrance every 10 meters on average. Considering results comparatively, we understand that the building-street interface of row houses and tenements supports more than twice the potential for building-street interaction than the rest of the buildings in the area.

The key observation from this analysis does not refer to the building types *per se*, rather to their morphological properties. More particularly, what is important to understand here is that the narrower the façade (and in effect the plot width), the higher the potential for a denser building-street interface is observed. The mean façade length for row houses and tenements in West Village is calculated at 8.4 meters. On the other hand, the remaining building façades are twice as longer with their mean length reaching as high as 22.4 meters.

Table 1. Row houses, old- and new-law tenements; door encounter rate (c.2013).

	Buildings	Doors	Tot. Façade Length (m)	Door encounter rate (m)
Row house	1324	2477	9523	3.8
Old-law tenement	244	523	2139	4.1
New-law tenement	101	326	1463	4.5
Historic	1669	3326	13125	3.9
Non-historic	982	2156	21982	10.2

The image of the streets

The aforementioned analysis is based on a theoretically evenly constituted urban streetscape; namely, it assumes an equal number of door entrances across all urban block-fronts in the case study area. Although this analysis provides an idea regarding the impact of morphological properties on the street interface, it does not capture the fine-grained complexity and morphological diversity of real urban settings. In order to configure a better representation of reality, the following section studies the built form properties at the scale of street segments. This time, analysis considers each segment side separately in order to study in greater detail the properties of the constituted *street interface*. Lying behind this is the proposition that whilst the configuration street network itself shapes – all things being equal – the varying distribution of people around an area, the building-street connections organise potential interactions between inside/outside (private/public) spaces. The study looks firstly at the *frequency*, and secondly, at the *mixture* in terms of morphology of building thresholds and the function each building contains. The study then also considers these results alongside straightforward space syntax measures of potential flows (as will be shown in section 5, below).

The survey record of building thresholds is illustrated in Figure 5. The map shows building entrances in the area of West Village coloured according to building use type. Considering the Village's historic split in terms of functional and morphological character – into the west waterfront on the one hand and the Historic District on the other (where the majority of rows and tenements lie within) –, results are summarised for each one of these areas to then be discussed comparatively.

To begin with, in order to form an overview of the building-street interface density for each district within the Village, we can summarise the number of building entrances and relate this to the total length of façades (Table 2). In terms of the building properties, the mean façade length of buildings within the Historic District is almost half the length of frontages in the non-historic Village parts. This in turn impacts on the street interface: within the Historic District, where pedestrians are likely to encounter a building entrance every 6 meters on average, in contrast to the significantly more sparse street interface of the west waterfront where building entrance spacing increases to 13 meters on average.

Following, in order to measure more precisely the *threshold frequency*, we can look at the number of building entrances per street segment side in relation to the block frontage length¹⁸. Figure 6 illustrates the calculated threshold frequency for street sides in West Village. Lighter colours reflect lower frequency and thus a looser street interface. As indicated by the threshold frequency map, the streetscape within the Historic District is constituted by a denser building-street interface (dark greyscale). The strong presence of rows and tenements which take over the

¹⁸ The block frontage length equals the sum of the length of building façades calculated separately for each segment side.

majority of historic blocks supports higher threshold frequencies, and thus higher potential for inside/outside encounters. In contrast, building thresholds become sparser towards the waterfront (light grey block sides). Building footprints in the waterfront blocks appear larger, and this implies longer building façades. This morphological feature, in combination with the sparse building-street connections, creates a less porous ground floor emphasising further the historical split of the Village streets.

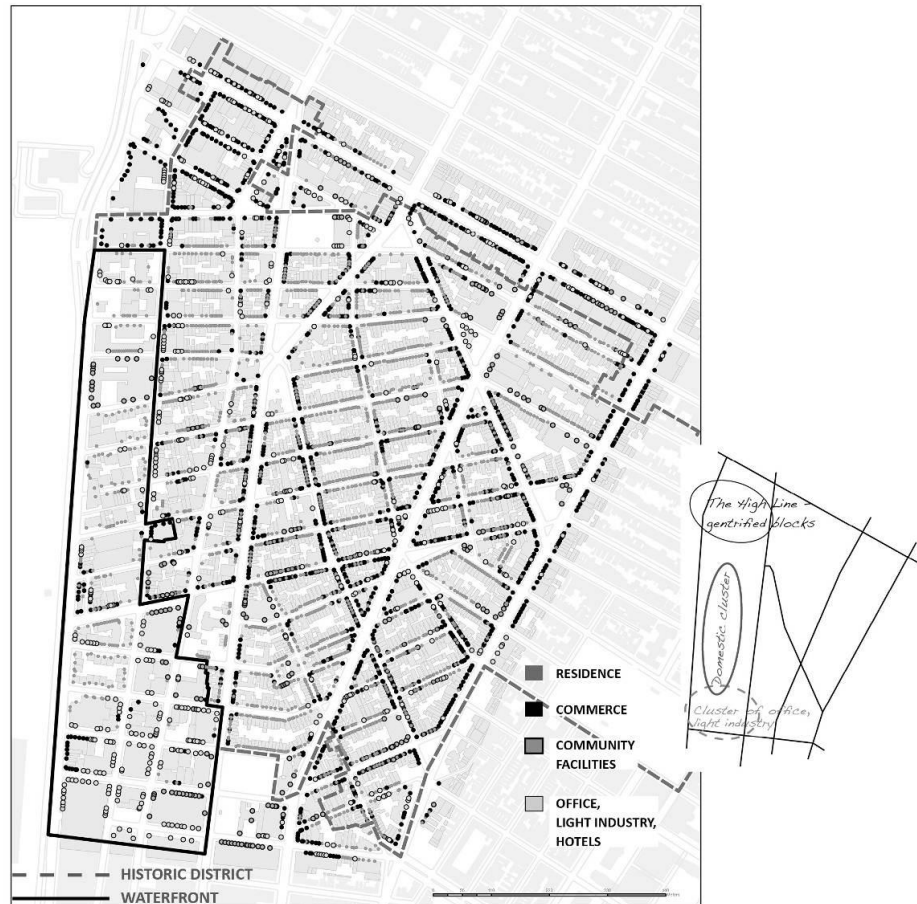

Figure 5. West Village - threshold map and land use distribution (c.2011).

Table 2. West Village - threshold record for Village parts (c.2011).

	Façades	Doors	Tot. Façade Length (m)	Mean Façade Length (m)	Door encounter rate (m)
Historic District	2354	4449	26742	11.4	6.0
Non-historic	494	1064	10871	22.0	10.2
Waterfront	249	518	6554	26.3	12.6

Figure 6. West Village - threshold frequency (c.2011).

The next step is to understand the street interface as an aggregate of varying uses overlooking at the street domain. Building use has an impact both on the morphology of the building-street interface, as well as on the social profile of streets. There are building uses which aim to engage the pedestrian and hence open up the building interior to the street domain visually or accessibly (like retail and commercial uses in general). There are also uses with a more private character which aim to protect the interior function from the pedestrian traffic. Depending on the uses aggregated within a block front, pavements become more or less private or public in their morphology; also, depending on the mixture in uses aggregated within a block front, pavements become mono-functional or mixed-use. These properties (morphology and function, respectively) have an impact on the potential social profile of the street segment.

Studying the threshold map of West Village, we can explore the social profile of streets within the Historic District and outside, firstly in terms of uses *per se*, and secondly in terms of the mixture of uses (Figure 5, Table 3). The most predominant uses within the Historic District are the domestic (57.2%) and commercial (32.5%) types. Retaining the historically more industrial profile, non-domestic uses in the west waterfront refer mostly to offices and light industry (60.9% of the non-domestic uses). In general, for parts lying outside the Historic District non-domestic thresholds cover the majority of pavements (64%).

Table 3. West Village - threshold use record for Village parts (c.2011).

	Façades	Doors	Domestic uses	Commercial uses	Community services	Other uses	Vacant	Stoops	Primary thresholds
Historic District	2354	4449	2547 57.2%	1430 32.1%	134 3.0%	308 6.9%	30 0.8%	908 20.4%	3447 77.8%
Non- historic	494	1064	353 33.2%	319 30.0%	109 10.2%	253 23.8%	30 2.8%	98 9.2%	927 87.1%
Waterfront	249	518	205 39.6%	63 12.2%	54 10.4%	182 35.1%	14 2.7%	58 11.2%	442 85.3%

However, the most important observation arising from this map refers to the mixture of uses. Looking at the distribution of thresholds, it is interesting to point out that within the Historic District, in many street segments a mixture of varying uses is observed across the length of a block frontage. In the waterfront district on the other hand, thresholds of the same uses seem to cluster at the block scale: see for instance, the offices and light industry at the south, the residential blocks moving northwards, and finally, the gentrified district of The High Line (see Figure 5). Here, it is of relevance to recall references that highlight the importance of ‘heterogeneity’ as a significant characteristic of urban life (Hanson and Hillier, 1987). Urban space becomes livelier and more sociable when it brings together in close proximity varying uses that support one another in everyday rituals (Jacobs, 1961, p.153). Functional mixture at a finer scale (like the building and the segment) is one of the features lost in the redevelopments of the waterfront area in West Village.

Functional mixture leads to morphological mixture of varying building-street relations. The private-public transition can be configured in terms of access in many ways depending on the level of privacy required by the building function¹⁹. A basic distinction of thresholds is considered here between *primary* and *secondary* ones (based on the work of Hanson, 2000; Hanson and Zako, 2007). Primary boundaries are direct entrances (the building line coincides with the plot line). Secondary boundaries refer to indirect building-street relations, where in order to access the building entrance a user needs to pass firstly from an additional space (like a staircase or a yard) bounded by a secondary threshold (like low or high fences). Table 4 shows the relation between building function and the type of building-street transition (direct or indirect). Commercial uses in the area of West Village have almost exclusively a direct relation with the street domain (94.5% primary thresholds). Offices, hotels and buildings with light industrial uses (land use category named ‘other’) also have in their majority direct building entrances (92.5%). Community service buildings (like schools and churches) have in some cases (22.6%) a protected and more private interface. Finally, as expected, domestic uses are the most prominent in having an indirect relationship with the street, with one out of three residences in the Village distinguishing the private interior from the public domain. Overall, the degree of privacy of the building-street interface depends on building use and purpose which in turn influence the morphological treatment of the private/public transition.

Morphological mixture is also an outcome of architectural variations. In this respect, morphological diversities are more likely to occur when a block frontage is the assemblage of many building façades. Consequently, building units with narrow façades (meaning more building units per block) and of different architectural styles contribute to creating a complex micromorphology on the street pavements. For example, row houses themselves present many morphological variations regarding the building-street interface. Ascending and descending stoops, grandiose or modest porticos, direct entrances, areaways etc., all consist variations of the row house interface based on architectural style. These morphological variations can create in turn different social situations. For instance, when accessibility to the stoop is free from barriers (like low railings), then stoops can work as informal places of social encounters (people meeting, seating, talking etc.). Likewise, a commercial use might extend outwards and take up parts of the pavement area. Looking at row houses and tenements in West Village, we can form an idea of the complex spatial relations that these building types can generate over time. Figure 7 shows varying threshold types for the row houses and old-law tenements (which have the narrowest façades). Data in Table 3 confirm as well the more significant presence of stoops within the Historic District, while the west waterfront is mostly constituted by direct entrances.

¹⁹ Consider here the varying levels from publicity to privacy as discussed by Newman 1972, 1975: from a social utility perspective a space can be characterised as ‘public’, ‘semi-public’, ‘semi-private’, ‘private’.

Table 4. West Village - threshold type according to land use (c.2011).

	Domestic uses	Commercial uses	Community services	Other uses
Primary thresholds	1953 67.3%	1652 94.5%	188 77.4%	521 92.9%
Secondary thresholds	947 32.7%	97 5.5%	55 22.6%	40 7.1%
Total Doors	2900 53.2%	1749 32.1%	243 4.4%	561 10.3%

**Figure 7. West Village - type of entrance for row houses and old-law tenements (c.2013).**

In a sense, analysis in this section has treated the block frontage as a morphological unit. It has been argued that the properties of the building-street connections within a block frontage regarding relate to the potential social encounters organised by the built form: blockfronts with denser and more diverse (functionally and morphologically) building thresholds are more likely to generate street liveability. Comparative analysis for the current historic and non-historic streetscape in West Village has suggested that the narrowest façades of historic building typologies support higher densities and mixture of building thresholds in relation to the solid, larger in footprint and often monofunctional non-historic buildings.

The role of the street network

Following these observations, it becomes of interest to explore the reasons why some street sections develop a vibrant and sociable interface over time and others fail to do so. This section discusses the role of street network in distributing functional mixture (and consequently morphological built form). The relation of land use allocation and street configuration has long been established by space syntax studies (Hillier, 1996, Chapter four; Hillier and Vaughan, 2007). According to space syntax theory, streets with higher potential for *accessibility* and

permeability are more likely to attract uses requiring higher footfall, like retail, and to generate ‘multiplier effects’ over time.²⁰

A straightforward way to address the potential relation of a street segment’s interface with its role within the street network is to group street segments based on their space syntax (‘syntactic’) values (high, medium, low) and then explore the features of thresholds for each group. Accordingly, Tables 5 and 6 show results from this analysis performed for the area of West Village. Analysis is calculated for the measure of ‘combined integration and choice’, both for the local and the city-wide context of street network performance: firstly, analysis addresses the walkable radius of 800 meters in order to estimate the performance of the street network at a neighbourhood scale; and secondly, the wider city surroundings are considered with analysis calculated for the whole of Manhattan (radius n). Results for both studied scales indicate that segments with higher syntactic values contain higher numbers of commercial thresholds (almost twice higher on average) in comparison to segments with low values. It is also interesting to observe that the percentage of secondary thresholds (namely entrances with a more private character) is significantly lower in segments with high values. In effect, it is indicated that in the case of West Village segments with higher potential for pedestrian traffic have developed a more public street profile.

In order to interpret accessibility and permeability (namely the configurational properties of the street network) in terms of morphology, the study looks in addition at the physical characteristics of street segments which might influence the chances for a street part to develop high potential in attracting pedestrian movement (and thus attract more urban-like uses). Jane Jacobs’s observations and interpretations provide a morphological hint regarding the characteristics of permeability: the author argues that short blocks enhance pedestrian flows, become livelier and consequently, support greater socio-economic mixture. Here, we interpret this morphological property of the built form (namely, the short block front) as a configurational property of the street network (short segment length). Indeed, looking at the syntactic map of the Manhattan street network illustrating the values for the measure of ‘combined integration and choice’ (for radius 800 – namely the walkable scale) we can observe that shorter block sides have measurably higher potential for pedestrian flows (Figure 8, Table 7). To examine this further we summarise the properties of building thresholds based on segment length (Table 8). Results confirm a potential impact of street segment length (and respectively of block size) in the land use allocation. In the Village, shorter segments (with length below 100 meters) have a prevailing non-domestic character, with the majority of commercial uses allocated there. Longer segments on the other hand are more domestic in their social profile and are constituted by more private building-street interfaces with secondary boundaries.

Pedestrian flows themselves confirm the role of street network in terms of the generated street liveability. As mentioned in section 1 above, spatial patterns are considered to give rise to the ‘virtual community’. The theory of ‘natural movement’ discusses how the configurational (namely, the relational) properties of the street network generate a primary distribution of movement patterns (Hillier et al., 1993). Movement patterns relate in turn with phenomena of co-presence. Physical co-presence is a fundamental precondition for social life to be generated in the street domain. Additionally, from a morphological perspective it is important to note here that not only the building function has an impact on the morphology of the building-street interface; the street function as a pedestrian route and its levels of utility also play a role in determining the type of the configured micromorphology of the sidewalk. For instance, depending on the levels of pedestrian traffic, building thresholds can occupy the pavement width (like in the case of stoops and areaways) or stand back at the building line (direct entrances) giving way to passing through users.

²⁰ In Hillier’s words (1996:127): “The urban grid through its influence on the movement economy is the fundamental source of the multifunctionality that gives life to cities”.

Figure 8. Manhattan - short/long segments and permeability. Segment angular analysis for combined measure of integration and choice for radius 800 meters.

Table 7. Manhattan - mean values for the measure of combined integration and choice for radius 800 meters according to segment length (c.2011).

	0 < 50 m	50 – 100 m	100 – 150 m	150 – 200 m	200 m and over
Segment Count	1138 14.6%	3851 49.5%	1151 14.8%	726 9.3%	919 11.8%
Combined integration and choice radius 800 m	31.408	28.715	18.548	10.666	3.487

The morphology of a sociable street interface

This paper was an effort to address properties of the built form that relate to street liveability. Stemming from the work of Julienne Hanson in ‘Urban Transformations’ (2000), where the author interprets spatial and morphological properties of the built environment as social properties of urban space, this study aimed to explore further the morphological features of a lively street interface. Considering building-street connections as potential points of social encounter between the ‘static’ (interior) and the ‘moving’ (pedestrian realm), between the private and the public, the study suggests that building thresholds reflect the potential vibrancy and sociability of the building-street relation, and accumulatively of the street interface.

Examining the case of West Village, the effort was to decode the role of urban components in bringing together the spatial and physical affordances for co-presence and social interaction in the area. To summarise the key observations, throughout the analysis of West Village it was discussed that the following built form properties are to be considered when aiming for a vibrant sidewalk micromorphology: i) the plot size; narrow plots mean narrow building façades which in turn increases the potential for a high threshold frequency across the block frontage; ii) functional mixture; the mixture of building uses within the block frontage length; iii)

morphological mixture; buildings with varying architectural styles and consequently varying treatment of the private/public transition.

Table 8. West Village - threshold use record according to segment length (c.2011).

	0 < 50 m	50 – 100 m	100 – 150 m	150 – 200 m	200 m and over
Segment Count	47 15.1%	172 55.3%	74 23.8%	10 3.2%	8 2.6%
Total length	1.723 km 6.2%	12.922 km 46.5%	9.480 km 34.1%	1.618 km 5.8%	2.058 km 7.4%
Total façades	124	1220	1065	184	254
Total doors	219	2322	2070	397	501
Domestic	86 39.3%	1012 43.6%	1317 63.6%	219 55.2%	266 53.1%
Non domestic	133 60.7%	1306 56.2%	731 35.3%	178 44.8%	234 46.7%
Commercial	105 47.9%	994 42.8%	418 20.2%	119 30.0%	146 29.1%
Community	4 1.8%	75 3.2%	93 4.5%	22 5.5%	48 9.6%
Other	24 11.0%	237 10.2%	220 10.6%	37 9.3%	40 8.0%
Blank	12 5.2%	209 9.0%	222 10.7%	70 17.6%	45 9.0%
Secondary	30 13.7%	346 14.9%	511 24.7%	93 23.4%	155 30.9%

In addition to these properties, it was highlighted that short segments (and thus short block sides) enhance pedestrian flows and consequently increase co-presence. Finally, the effect of the street network in a street's profile has been discussed: movement patterns influence land use allocation and levels of pedestrian traffic having and impact on the morphology of the building-street connection. In other words, the street interface is the morphological unit where all urban components (building, plot, street) overlap, work together and potentially interact.

Overall, the study emphasised the role of density as well as of functional and morphological mixture in building thresholds within a block frontage as key properties for creating a sociable street interface. Considering the post-modern redevelopments in the west waterfront in West Village it can be understood that these urban blocks present the opposite morphological features: with building footprints covering large plots (which can be sometimes equal to the entire whole block area), lower threshold frequency and a more opaque ground floor, concluding that these redevelopments present far less potential for functional and morphological heterogeneity, for the oft desired 'urban diversity'.

Abstract. *The present paper examines the morphological aspects of two developments of “Projeto Orla” in Brasília – Brazil, in order to understand how the configurational characteristics affect the local vitality. The relations between the constructed form and movement are explored, following the concepts of the Theory of Social Logic of Space or Space Syntax. The variables present in the research are land use, relation between full and empty spaces, density, axial structure, legibility/orientation, blind spaces, transport, infrastructure, imaging potential, monumental scale and bioclimatic aspects, with focuses in four dimensions of architecture: perception of the place (“topoception”), functionality, copresence and symbolic aspects. The findings allow us to place the area under study within the paradigms of formality (Brasília Palace) and urbanity (Pontão do Lago Sul), thus fostering the discussion about the differences between pre-modern and modern cities. In addition, it is possible to use these findings for project exercise, conceiving strategies or recommendations that can be applied to the implementation of the remaining developments.*

Key Words: Morphological features, vitality, formality and urbanity.

Introduction

Projeto Orla is an urban development program alongside the shore of Lake Paranoá, in the city of Brasília – Brazil. This article researches two developments of Projeto Orla and their relationship with the city. Out of the eleven developments originally designed, the Brasília Palace Complex and Pontão do Lago Sul were selected for discussion, as they are the only ones which have already been implemented in most part.

The relationship between the traditional city and the city resulting from modern urban planning is explored, and Brasília is exemplary in that regard. Thus, it would be a way of analysing the reasons associated to the space which potentially lead to the abandonment of certain places. In addition, the studies seeks to research the relevance of spatial configuration in order to explain – or at least contribute to the debate – the success (or lack of) of certain areas, which may provide insight for issues of urban dynamics and decline of these urban spaces.

Therefore, we believe it is possible to evaluate the success or failure of these developments based on a preliminary analysis of configurational features, such as: land use on the immediate surroundings, relation between empty and full spaces, density, street infrastructure, distance from the urban center, segregation vs. integration etc.

Methodology

Theory and concepts

The conceptual scope adopted in this research is based in the Technique of Dimensional Analysis, which allows the morphological interpretation of spaces, based on six dimensions, or

aspects: functional, financial-economic, expressive-symbolic, bioclimatic, copresencial /sociologic and topological perception (Holanda et al., 2005; Holanda, 2010). The study, whose aim is to analyse the lake shore and its relation to the city, undertakes the view that the reading of the urbanization process and the dynamic of the resulting spaces can be better understood based on its morphologic dimensions.

In order to understand the connection between urban morphology and the different processes associated to it, we used the concepts of formality and urbanity (Holanda, 2002). The formal spaces are those whose configuration is less prone to encourage interpersonal encounters than urban spaces. This is a fundamental aspect in the organization of the elements of space that can either foster or hinder vitality, taking into account the arrangement of the parts in relation to the whole (Medeiros, 2013).

Methodology/procedures

A configurational analysis of the spaces is carried out with a qualitative emphasis in order to reach the scope of the results. An exploratory reading of the developments and their relation to the city is established considering the identification of existing typologies and land uses and their relation to the space, the presence of a street network and its degree of articulation, the definition of integrated or segregated areas, amongst others. Such findings encourage the construction of hypothesis, questionings and paths to subsidize future researches about the theme.

In order to do so, we start from the basic premise that possibly the configuration of these spaces and their articulation with the city are predominant aspects for higher or lower vitality of the waterfront of Lake Paranoá. Thus, the analysis of the two developments is carried out on a micro and macro scales. The first is restricted to the legal area of each development and the second corresponds to a radius of 2 km from the geometric center of the unit. This radius of coverage was defined so as to cover the main roads as well as the land uses and occupations of the immediate surroundings.

In the micro-scale, aspects of land use, relation between full and empty spaces, the existence of barriers, hygrothermal comfort, sense of security or insecurity, density and infrastructure are addressed. On the macro scale, four dimensions / aspects are analyzed for being considered most relevant to understand the relationship of the developments with the rest of the city: topological perception (performance of configuration regarding the legibility and orientation – cf. Kohlsdorf, 1996), functional (performance on the operational level of the space), copresence/ sociological (performance regarding features which foster or restrict interpersonal encounters) and expressive-symbolic (the capacity of places to forge in emotional and affective bonds in people).

Interpretation of the axial map of Brasília and its surroundings, with special attention to copresence aspects (Source: DIMPU/UnB with adaptations by Medeiros, 2013);

Analysis of the Master Plan for Transport and Mobility of the Federal District – PDTU/2011.

Formality vs Urbanity

According to Holanda et al. (2005), “human settlements throughout history, from indigenous tribes to the great metropolis, can be classified according to the nature of their syntactic

attributes". Therefore, the author uses concepts of formality and urbanity in order to name the morphological types from the standpoint of Space Syntax Theory (Hillier e Hanson, 1984; Holanda, 2002; Medeiros, 2013).

"Formality" is a word derived from 'formal', related to 'form' – 'the outer limits of the matter that constitutes a certain thing, and that grants it a configuration, a peculiar aspect' – but that in a particular way: "that is not spontaneous; that is attached to pre-established formulas; conventional". "Formality" is also "a specific way of proceeding, that which is conventional, routine". In turn, "urbanity" refers to the city as a physical reality, to which the qualities "courteous, friendly, with continuous negotiation of interests" is added. (Holanda et al., 2005).

In regard to the built space, formality has been consistently characterized by factors such as: a) maximization of open spaces on the total area of the settlement, b) higher percentage of blind spaces, c) an extremely integrated or extremely segregated axial structure/ high or low levels of incoming streets (as opposed to an intermediate position in regard to this scale of variability), d) low intelligibility, e) low variety of land use, f) higher presence of empty spaces compared to full spaces, g) low density, h) great distances to the urban center, i) socio-spatial isolation/segregation, j) the monumental/symbolic aspects are the main object, etc. The features that refer to urbanity encompass characteristics that are opposed to those listed.

The 'traditional' city

The so called "traditional" city differs from the standards of "modern city" advocated and embodied in the 50s and 60s of the 20th century. Solutions such as Brasilia and Chandigarh broke the historically recurring urban model, assuming more formal and less urban features.

In the traditional cities, there is a balance between full and empty spaces, in a proportion defined by many authors as being 50/50. The concept of full space refers to the private spaces, such as residences and offices, etc., and the empty spaces refer to public areas, including, but not limited to, streets and squares.

Both in the regular grid pattern as well as in organic ones, lots are contiguous and distributed in blocks, having a direct relationship with the street. This allows a greater flow of people and hence larger amount of interpersonal exchanges in the open spaces. Such configuration is what makes us consider a city to be "alive".

Moreover, attributes such as the variety of land uses and activities, high density, integration (at least in the central parts), higher percentage of open spaces, for example, are common features in "traditional" cities. According to the literature (Jacobs, 1970; Salingaros, 2006; Alexander, 2013; Gehl, 2013), these features make settlements more urban (and therefore less formal), awarding greater vitality to open spaces.

Brasília: a modern city

In the modern city, despite the eventual use of regular grids, lots are not distributed in blocks, but in isolation, with no direct relationship with the street. Here the empty spaces, represented by green areas, paths and terraces prevail. This relationship is the big break that the modern movement brought to the way of thinking about the city: full spaces correspond to 30% of the total area of the city on average.

There are lessons to be learned from the urban design of the Pilot Plan of Brasilia especially regarding the features that confer strong global legibility. However, for the object of study of this article, we aim to examine the design issues that weaken the local dynamics, especially those arising from the fragmentation of the city, i.e., the disruption its fabric. The scenario is the product of the configuration of space, such as the presence of large voids that result in open spaces with little or no vitality.

With regard to the urban system in its entirety, over the years Brasília became a "morphological mosaic" (Holanda et al., 2013), where various morphologic types coexist. Its classic modernism immediately provided a sharp contrast with the vernacular configuration of the surrounding urban centers (Planaltina from 1810 and Brazlândia 1930) and with the farms close by.

The capital is nowadays a "polynuclear metropolis" (Holanda, 2002; Holanda et al., 2008) and the classical modernism or "modern city" is restricted to the Pilot Plan, where less than 10% of the inhabitants of the Federal District live (IBGE, 2010). However, the region concentrate 44% of the jobs in the Federal District, higher level of income and benefits of urbanization, which legitimizes its role as Centre for Commerce and Services, that is, the main active urban center.

The overall structure of Brasília discloses a system characterized by eccentricity, dispersion and socio-spatial segregation (Holanda et al., 2008; Holanda, 2010). The trends of fragmentation are not restricted to the macro-scale, they are also identified in the micro-scale, present in the internal areas of the Pilot Plan.

Projeto Orla

The project under study, Projeto Orla, – also known as Master Plan for the Occupation of Lake Paranoá Shores or Plan for Touristic Ordering and Structuring of Brasília – was elaborated by TCI Planejamento, Projeto e Consultoria Internacional Ltda., a company hired by the Government of the Federal District – GDF and by Embratur in the year 1992. The goal was to forward the use of the remaining free areas located on the shores of Lake Paranoá, increasing its touristic, economic and cultural relevance. The development encompasses a broad project for the whole area around the lake, developed in partnership with the private initiative, having as the main goal the implementation of quality public spaces.

In its first phase, the ten developments were supposed to be implemented, in an area of approximately 78,000.00 m². In 1995, this number was increased to eleven. In addition, a promenade, called 'boulevard', was designed, in order to integrate them all. These attractors were planned to have diverse land uses and activities, including leisure, entertainment and lodging, which would include hotels, restaurants, piers, an area for playing sports and support facilities for water sports, cultural centers, museums, concert venues and a heliport.

Connecting the eleven developments, four circulation systems were proposed, the first being a pedestrian boulevard, the second a cycle lane, the third option would be a low speed street for cars, and last, the public marinas and small piers, providing infrastructure for water transport.

However, until the present moment, Projeto Orla has not lived up to its goals. Due to the slow pace of the Government and the lack of political will, the implementation was partial. The circulation systems proposed, for example, were never executed.

Brasília Palace Complex

Description of the area and the development

Brasília Palace Complex – Development 3 (Figure 1) is located between Clube da Imprensa and Bosque dos Leões, near the Alvorada Palace. The original concept encompassed an area for 4 hotels, amongst which, Brasília Palace, designed by Oscar Niemeyer. The place is characterized as a cultural center, where the Art Museum of Brasília – MAB, the Acoustical Shell, and the Pavilhão da Bienal e Arte are already in place. Together, the three of them would be a part of the Praça das Artes (literally translated as Arts Plaza). In addition, an area for commerce, pubs, restaurants, cinemas and marinas was previously envisioned. The urban project was registered and partially implemented. However, nowadays the place is partially abandoned.

The flats and hotels that are part of the complex are mostly surrounded by walls and its recreational areas invade the shores of Lake Paranoá, forming a barrier that prevents the flow of pedestrians within the complex and the free access to the waterfront. Such is the situation of the development called Ilhas do Lago, "Lakeside" (Figure 2), "Premier" and "Royal Tulip" (formerly "Blue Tree"). The exception is Brasília Palace Hotel, which has a higher permeability, since it is a building on pilotis and grants free access to the public: it is the only one that kept a desirable distance from the water surface.

Figure 1. Aerial photograph of the Brasília Palace Complex – Development 3.

Configurational analysis (micro scale)

Roughly speaking, these typologies act as barriers, due to the walls and blind spaces, thus affecting the articulation and interaction between the public spaces. These free spaces for the general public have few buildings, which are isolated and distant from one another, and the empty spaces prevail. However, due to the total absence of street furniture, except for the streetlights along the waterfront, the place is dark and lifeless at night – unless there is an event happening at the Acoustical Shell.

It is possible to notice that the flats and hotels are taking over the place, and the public areas are in a state of partial abandonment without the assistance and infrastructure necessary for becoming a touristic and cultural complex. Moreover, there is no diversity of uses, once the project was not fully implemented. The immediate surroundings present homogeneity, with a predominance of institutions - Press Club, Air Force Club - and residences - Alvorada Palace and Vila Planalto.

Despite the large parking lots, there are some clusters of trees scattered around the area. These trees and the breeze from the lake generate a certain hygrothermal comfort. However, the issue could be substantially improved with the addition of trees to the parking lots and the implementation of the landscape project previously designed for the site.

There are virtually no well-defined sidewalks or paths, except for the cemented promenade being built by GDF along the waterfront. However, it does not meet the requirements of an environmentally friendly coverage (higher permeability, reflection X absorption of sunlight etc.). Moreover, the materials and colors do not define the routes well and do not aesthetically improve the site.

Configurational analysis (macro-scale)

When analysing the development in a macro scale, that is, in relation to the rest of the city, it is possible to notice that Development 3 is very central, once it is near Vila Planalto, in the

surroundings of the Esplanade of Ministries. The street that gives access to the Esplanade, N1 East, is one of the options for reaching L4 North and the Hotel and Tourism Road, the main Access to the complex.

Figure 2. “Lakeside Convention Center and Resort” – Development 3.

Although Vila Planalto works as a good reference point to reach the desired location, the signs of way are not very clear for those who are going there for the first time. After reaching the access road, one has only to follow it to the end, which may also cause certain insecurity, since there are no reference points or visual landmarks – there are far more empty spaces and the existing constructions are mainly horizontal. Thus, we can conclude that although the development is located in a privileged area and the route is fairly straight forward, the place lacks visual legibility (strong identity) and adequate signs, which could offer better conditions for orientation.

In terms of functionally and accessibility, the only ways to reach the destination is on a private vehicle or by bus, there not being any cycle lanes or any other means of public transportation. The water transport is only destined to those who have their own vehicles, despite the presence of a pier on the site.

According to data from PDTU-DF/2011, only two bus lines go through the complex. They are: 1401C (Circular - Vila Planalto – L2 / W3 Norte) and 1042C (Circular – Esplanada / Palácio do Jaburu / Palácio da Alvorada).

Copresential aspects are tightly associated to a higher or lower level of integration of a certain area with the rest of the city. Thus, the integration measure ‘refers to the higher or lower accessibility between the parts of a city, based on the minimum number of turns of a route between two points’ (Holanda, 2010)

“These values can be expressed numerically or by a color scale with a gradation from red to orange to green to blue – where the axis with a higher integration value tend to red and the lower to blue” (Medeiros, 2013).

Therefore, analysing the Axial Map of Brasília (Figure 3), it is possible to notice the main roads that grant access to the complex are green, that is, they have an intermediate level of integration (between 0,647 and 0,809), except for the axis S1 East and L4 South – of orange color – which have a higher integration level (between 0,809 and 0,970). Most of streets inside the development under study are represented by light blue lines, since they present low level of integration (between 0,486 and 0,647). Thus, it is possible to conclude that the area under study is more segregated than integrated, being closer to the concept of formality than urbanity.

The symbolic aspects are related to the architectonic elements that translate in images that represent the site, such as the Brasilia palace Hotel (whose name extends to the whole site), the Acoustic Shell and the MAB. Therefore, we can come to the conclusion that the place has a

strong imaging potential, but the symbolic aspect needs to be better explored and valued, specially due to its proximity to Alvorada Palace, an icon of Brasília.

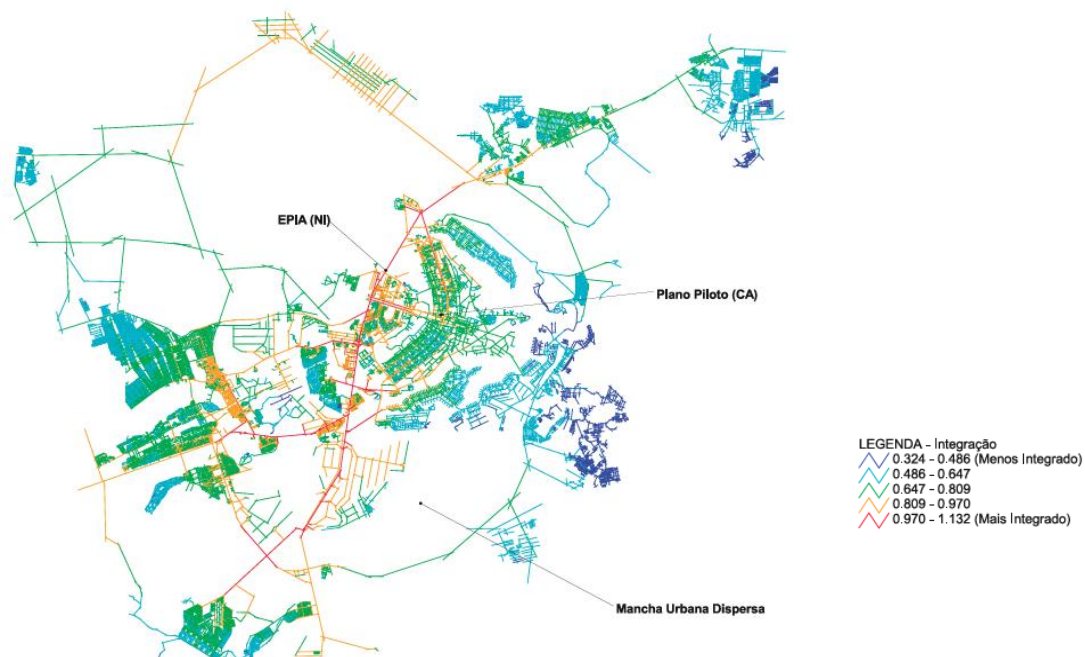

Figure 3. Axial Map of Brasília – global integration Rn.

Pontão do Lago Sul

Description of the area and the development

Pontão do Lago Sul – Development 11 (Figure 4) is located close to the Costa e Silva Bridge. Since its conception, the development was created to house restaurants, pubs, small stores, antique shops, arts and crafts shops, equipments for sports, and a pier for boats. The place is run by private entities and has been attracting an average of seven thousand people on weekends.

Figure 4. Aerial photograph of Pontão do Lago Sul – Development 11.

Configurational analysis (micro scale)

On quick configurational reading of the entire Complex, it is possible to notice that the use is mainly commercial, but it is set in a region that lacks establishments of this kind, since the residential use is prevalent in South Lake Administrative Region. Despite the predominance of places dedicated to the Classes A and B, currently, some kiosks have emerged as more affordable alternatives for Classes C and perhaps D.

The buildings are concentrated along the waterfront and are interconnected by paths for pedestrians. Although the floor coverage of these paths not being permeable, there is a concern with materials and colors to better define the paths and aesthetically improve the place. In general, the wide open spaces for the public already have a reasonable number of constructions, but empty spaces still prevail. These buildings are opened to the public spaces with their porches and balconies mainly facing the existing promenade along the waterfront. Therefore, the open spaces prevail over the blind spaces.

The site is well equipped with street furniture, to include bins, benches, street lighting, ATMs, etc. Therefore, the site works well, both in during the day and at night, when the sense of security is constant.

In regard to bioclimatic aspects, the space has a fairly good quantity of trees, however the asphalt surface of the parking lots is what prevails. There, the tree coverage is still young, and has not yet reached an appropriate height. The breeze and moisture from the lake help hygrothermal comfort, especially at night when the air is cooler.

Configurational analysis (macro scale)

From a macro perspective, the place is quite central and stands out in the landscape as it is located on a peninsula of Lake Paranoá, right next to Costa e Silva Bridge. The main access roads are Avenida das Nações, Dom Bosco Park Road - EPBD and finally Costa e Silva Avenue, the access road to the development (there is adequate signs).

Despite the buildings being mainly horizontal in Setor Habitações Individuais Sul - SHIS and the large green area that separates from the main access road, Costa e Silva Bridge serves as a good reference to reach the site, and it is possible to see much of the gastronomic complex. In addition, the entrance portico acts as an important visual marker, although some consider it of questionable taste. Thus, we can conclude that in addition to its privileged location and few turns during the route, the signs on the route are present in adequate number and there is great visual legibility (strong identity), which offers good conditions for orientation.

With regard to the functional aspects, the only way to get to the venue is a private vehicle or bus, since there are no cycle lanes (inside and outside the complex) or any other means of public transport. The water transport is only destined to those who have their own vehicles, despite the presence of two or three piers on the site (Figure 5).

Figure 5. Pier of Pontão do Lago Sul.

According data from PDTU-DF/2011 there are twelve bus lines that serve the development: 0772i, 1005i, 1005v, 1007i, 1473i, 1473v, 1474i, 1474v, 1477i, 1477v, 1971i and 1974i. All of them go through the Pilot Plan, being that six go through the city of Paranoá, four through São Sebastião and two through Agrovila.

In regard to the copresential aspects, analysing the Axial Map of Brasília (Figure 3), it is possible to notice the main roads that grant access to the complex are green or light blue, that is, they either have an intermediate level of integration (between 0,647 and 0,809) or a low level of integration (between 0,486 e 0,647), except for the south portion of Avenida das Nações – orange line – which has a higher integration level (between 0,809 and 0,970). All the streets inside the development under study are represented by light blue lines, since they present low level of integration (between 0,486 and 0,647). Thus, it is possible to conclude that the area under study is more segregated than integrated, being closer to the concept of formality than urbanity.

In regard to the symbolic aspects, we must mention Costa e Silva Bridge, designed by Oscar Niemeyer as the main structure that represent the immediate surroundings, as well as Brasília. The bridge was chosen to become a brand of Projeto Orla, since it embodies the connection between the city and the lake. Therefore, it is possible to say that the place has imaging potential.

Conclusions

The article examined two developments of Projeto Orla – the Brasilia Palace Complex and Pontão do Lago Sul – and their articulation to the city of Brasilia (Brazil). Based on the findings obtained, Table 1 was drafted to summarize the attributes examined in the configurational analysis, so as to facilitate the compared reading and the placement of each development within the framework of either formality or urbanity.

Based on the analysis of the previous items, the qualifications identified are listed below. In some cases, the feature for a certain development can be considered in an intermediate level. In that case, for this attribute two concepts we marked, but they were not counted in the total sum presented at the end of the table 1.

In face of the results obtained, we can conclude that the Brasília Palace Complex is a space of extreme formality, since it has almost all the morphologic attributes associated to this concept. Therefore, it is a place less favorable to interpersonal encounters and potentially presents little vitality, except during some events that are held at the Acoustic Shell.

In the case of Pontão do Lago Sul, there was a relative balance between the number of attributes associated to each concept. However, the concept of formality prevailed by a small margin. Thus, although this development is more closely associated to the concept of formality, it still has more urbanity attributes that make it an environment more prone to the flow of people and their interactions. Therefore, it is a place of great vitality in some periods of the day, for most of the week.

Nevertheless, Pontão do Lago Sul may deserve the classification of urban magnet, present in the Space Syntax Theory, to explain some developments which show some vitality, despite not having the configurational attributes favorable for such. They are potent flow and movement attracting developments: not only do they concentrate commerce and services, but also refer to a certain social status, in no small part due to the security of its facilities – which seems to fit perfectly to the scenario of Pontão do Lago Sul. After all, the surrounding fence and entrance portico, the security guards all around and the prices practiced at the pubs and restaurants are elements which clearly restrict the access.

The city is socially diverse and heterogeneous, historically built by differences and these reflect directly upon the configuration of its spaces. This way, the spaces are built according to this variation, directed to the public it is meant to serve. However, the spaces must not be excludent, after all it is a public space, and every citizen has the right to enjoy them. In the

specific case of Projeto Orla, free access to Paranoá Lake must be granted to everyone, without causing any embarrassment or hindrances, created by barriers of any kind.

Table 1. Attributes of formality x urbanity.

ATTRIBUTES	BRASÍLIA PALACE COMPLEX		PONTÃO DO LAGO SUL	
	FORMALITY	URBANITY	FORMALITY	URBANITY
Land use	Low diversity		Low diversity	
Full X empty spaces	Predominantly empty		Predominantly empty	
Density	Low density		Low density	
Axial structure	Low integration		Low integration	
Legibility /orientation	Intermediate	Intermediate		High
Spaces: blind x open	More blind spaces			More open spaces
Transport	Predominantly private		Predominantly private	
Infrastructure	Insufficient			Satisfactory
Socio-spatial segregation	Intermediate	Intermediate	High	
Imaging potential		Strong	Intermediate	Intermediate
Interpersonal relationship	Intermediate	Intermediate		Human relations prevail
Bioclimatic	Intermediate	Intermediate		Good performance
Total	07	01	06	05
Results	Very formal space		Formal space

Mapping urban space based on visual perception

Yue Zhuang, Wowo Ding

School of Architecture and Urban Planning, Nanjing University

E-mail: ppmountain@163.com, dww@nju.edu.cn.

Abstract. *Urban space plays a very important role in urban morphological studies, while 2-dimension based urban patterns were often used as a research basis. Many researchers have tried different ways to make urban pattern with 3-dimensional information as study basis, however the results were not entirely satisfactory until now. Isovist is a method used for testing visibility of the plan or space, which has been used for describing spatial character of urban street. Along that line our research tries to develop a method to read urban pattern with height information, to create better urban physical space model for further spatial study. 3D urban physical space model is built by Matlab, and new database for the space is formed simultaneously. Our approach is setting a viewpoint forming a Viewsphere within the urban physical space built by Matlab, which can measure the urban space and collect 3D information as well. Based on isovist idea, new mapping method is developed. This paper tries to show our working process and do some analysis of the data.*

Key Words: *Urban space, 3-dimentional information, isovist, viewsphere.*

Introduction

Mapping of urban space is an important part in urban morphological studies, while 2-dimension based urban patterns were often used as a research basis. Many trials have been made to include the 3rd dimension in the mapping method; however the results were not entirely satisfactory until now. Isovist is one of the mapping methods based on visual perception. It has researches based on both two dimensional and three dimensional.

Benedikt (1979) is the first to introduce the isovist to architecture field. An isovist is the set of all points visible from a given vantage point in space and with respect to an environment. The shape and size of an isovist is liable to change with position. Numerical measures are proposed that quantify some salient size and shape features. These measures in turn create a set of scalar isovist fields.

After his introduction, many space analysis methods based on isovist have been developed. Turner et al (1999) described a new method for syntactic analysis of isovists that complements existing space syntax methodology by allowing the automatic generation of integration values from 3D CAD models. Batty (2001) began with a formal representation of isovists and their fields, introducing simple geometric measures based on distance, area, perimeter, compactness, and convexity. He suggested a feasible computational scheme for measuring such fields, and illustrated how we can visualize their spatial and statistical properties by using maps and frequency distributions. Turner (2003) uses an agent-based model of visual actors within the configuration to analyse an urban environment. Llobera (2003) used Geographical Information Systems (GIS) to study human visual space based on isovist. Arthur et al (2005) studied relating the dependent variables of 'spaciousness' or 'enclosure' to independent variables calculated from the mathematical construct of an 'isovist'.

But the isovists used in all these studies above are two dimensional and so do not test for height. Many trials have been made to include the third dimension in isovist studies later. Teller (2003) introduced a mathematical modelling technique that is capable of mapping the variation of the sky visible from points distributed throughout space. It is based on spherical projections and, more specifically, on measures applied to spherical views. Compared with existing field-oriented approaches (isovists, e-partitions, and so on), the main advantage of this method lies in the fact that it is truly three-dimensional. Fisher-Gewirtzman (2005) introduces a model 'spatial

openness index' (SOI). It is a quantitative metric – expressed in terms of 3D visual spatial information: it measures the volume of free spaces potentially seen from a given point. In addition, it enables the simulation of weighted landscapes for a more realistic estimation of the view. This model can also be described as a 3D isovist. It enables the ranking of alternative built-up configurations. Yang (2007) developed a new tool 'Viewsphere analysis' to test how a GIS-based 3D visibility analysis can be conducted to evaluate different urban design scenarios.

In all these 3D-isovist methods, people studied mostly on the sky open index of a space, but none of them collected the detailed shape of the space. This paper finds a method to collect the detailed data of skyline of a street, and analyze the data of different space to find the meaning of the data.

Method

We use MATLAB to collect the data of the street skyline from one viewpoint. (figure 1) Starting from the viewpoint, to the skyline, a series of rays is generated. The horizontal angle between two rays is one degree. And the degree is recorded as " α ". For every ray, the intersection points between the ray and the building are extracted. The horizontal distances between the viewpoint and the intersected points are calculated and the minimum distance is recorded as " d ". The angles of elevation between the viewpoint and the intersected points are calculated and the maximum angle was recorded as " θ ".

Setting the angle of rays as X-axis, the distance as the positive Y-axis, the angle of elevation as the negative Y-axis, the Street Space Outline Diagram (SSOD) is generated (figure 2).

There are two curved lines in the diagram, which show how the distance and the elevation angle changes correspond to the change of the horizontal angle. The upper one shows the distance changes from far to near, and to far. After a break, repeat the process, and then appear another break. This means from a viewpoint in the middle of street, we can see how the buildings along the two sides of street approach or away from us. The nether one shows the elevation angle changes from 0 to nearly 40 degree, then back to 0. After that, repeat the process. This means from a viewpoint in the middle of street, we can see how the skylines of the buildings along the two sides of street become up and down. Both of the two lines in the diagram are symmetrical. It reflects the symmetry of the street model. Comparing these two lines, they changes synchronously. It reflects a kind of regularity of the street model.

Figure 1. Formula used to collect the street outline data.

Figure 2. Street space outline diagram (SSOD).

This is the basic model of a street. The diagram displays some characteristics of the model, but it may include some more information in it. So we would like to test some more models to find the potential uses of the diagram. And this model may be used as the standard one to judge the new characteristics of the subsequent models.

Experiment

We usually get the third dimensional information through axonometric drawing or perspective drawing. It is a direct viewing, but do not have accurate data. This time, we try a different method mapping the space including the third dimension, and expect to find some more information hidden behind the normal view.

We draw 28 Street space models, which is abstracted from the real world, to do the experiment. Figure 3 is the axonometric drawing of the models. Figure 4 is the plans of the models. Figure 5 shows the Street space outline diagram (SSOD) of the models. Each model is drawn in a square. It includes two parts, the building and the viewpoint. The viewpoint is exactly in the middle of the square. SSOD is calculated in MATLAB.

Figure 3. Street space models.

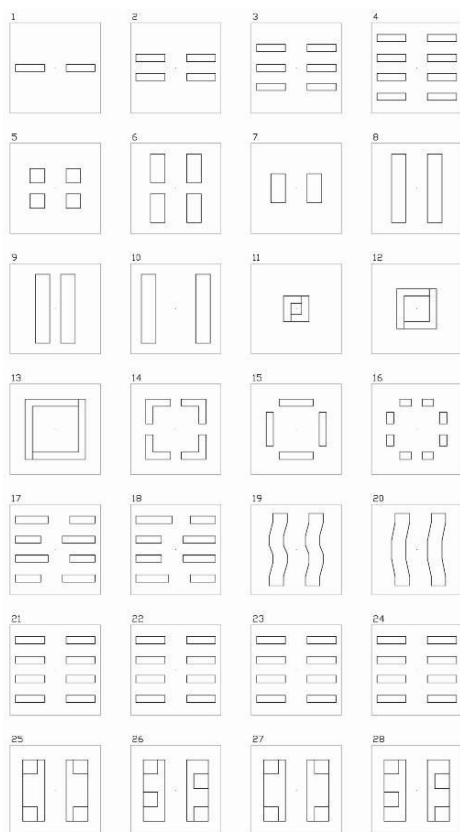

Figure 4. Plans of models.

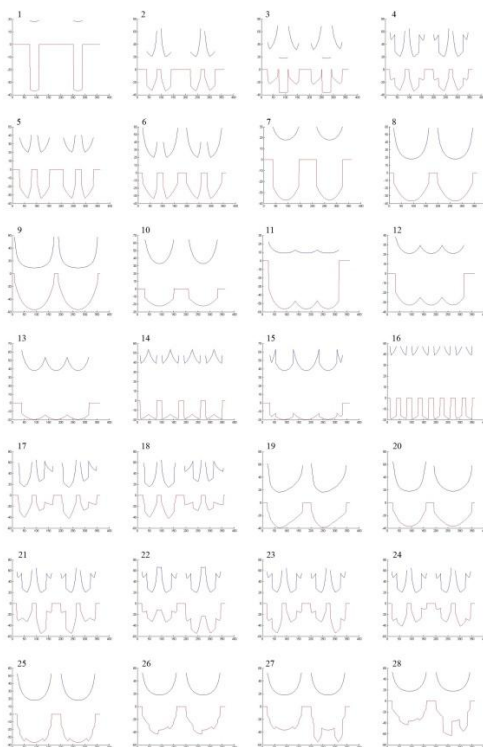

Figure 5. SSOD of models.

In order to find the rules between the model and the SSOD, we compare figure 4 and figure 5. In SSOD, the upper line means the horizontal distance change relative to the horizontal angle. The nether line means the vertical angle change relative to the horizontal angle.

From model 1 to model 4, the number of buildings increases. Relevantly, in SSOD, the upper line separate to several pieces or have several peaks. When the viewpoint is facing a side of building, the piece of line may be very short, because from that viewpoint we may not see other side of the building, but only one side of it. The lines connect together doesn't mean that the buildings are connecting, just because we may not see the break from that viewpoint. So we see the number of peaks not the number of pieces of lines as the character. The number of peaks corresponds to the number of buildings. One building refers to one peak; two buildings refer to two peaks, and so on. The nether line's peaks are also corresponding to the number of buildings. We can judge how many buildings are there in the street according to the peaks of line in the diagram.

From model 5 to model 8, the length of the buildings facing the viewpoint increases. Relevantly, in SSOD, the length of the upper line increases too. The nether line does not have significant change. Another discovery is that if the viewpoint is facing the corner of building, the peak of line is sharp. Oppositely, if the viewpoint is facing the side of building, the peak of line is smooth. We can judge the length of a building according to the length of the lines in the diagram, and decide whether the viewpoint is facing the side of building or to the corner of a building according to the shape of inflexion on the line in the diagram.

From model 9 to model 12, the distance from viewpoint to building increases or we can say the street become wider. Relevantly, in SSOD, the upper line has bigger break if the buildings are separate or deeper fold if the buildings are connected. But the nether lines rarely have difference. We may judge the width of a street according to the size of the breaks in the line. But it is not so obvious. So we may not see it as the character of the diagram.

From model 13 to model 16, the breaks of building increases. Relevantly, in SSOD, breaks of the upper line increases, and the fold of the nether line increases. The same with model 1 to model 4, the number of lines related to the number of buildings, no matter whether the buildings are along the street or around the viewpoint like a circle. But there is a problem that if the buildings are connected together and they have so many turning point, it is difficult to judge how many buildings there are. The connection between number of buildings and number of lines or peaks is only suitable for simple shaped buildings.

From model 17 to model 20, the buildings alongside the street have advance and retreat. Relevantly, in SSOD, both the upper line and the nether line are not symmetrical anymore. They change corresponding to the advance and retreat. If the building advances, the curve becomes smaller. If the building retreats, the curve becomes larger. Both the upper and the nether lines change synchronously. We may judge whether the buildings are ranged in a line along the street according to the synchronous change of both the two lines in the diagram.

From model 21 to model 24, the plan patterns of the models are all the same, but the height of building in each model are different. Relevantly, in SSOD, the nether line changes correspond to the height of building. If the building is taller, the curve becomes larger. If the building is shorter, the curve becomes smaller. But the upper line has no difference. The two lines do not change synchronously. The nether line which is the performance of the angle of elevation of the skyline is sensitive to the height of building. We can judge the building height according to the solos change of the nether line in the diagram.

From model 25 to model 28, the buildings have both tower and annex. One building has two kinds of height. Relevantly, in SSOD, the nether line changes correspond to the height of towers. But the line is not so regular. It seems as a mixture of two curves. One is corresponding to the height of the annex; another is corresponding to the height of tower. But the upper line has no difference. The two lines do not change synchronously. We can judge the building height according to the solos change of the nether line, and decide whether the building has only one tower or have both tower and annex according to the regularity of the nether line.

The most interesting part of this series of models is model 4 and model 21 to model 24. These five models have exactly the same plan. As we usually describe a space using plans, which do not have the height information, we can not find the difference between them. But from SSOD, we can see the difference from the lines in the diagram.

Through all these analysis, we can summarize the rules between SSOD and the models. The number of peaks refers to the number of buildings. The size of every piece of curves refers to the length of buildings. Synchronous change of both the two lines refers to the advance and retreat of buildings along the street. The solos change of the nether line refers to the height of buildings. We can grasp the main character of the street from SSOD without seeing the plan or the axonometric drawing, if the street pattern is quite simple. We can even tell what kind of buildings are there along the street, only by watching the lines in the diagram. But the models in this experiment are abstracted from the real world. They are not the real world. If we use real urban street to do the calculation, it may be not so easy to recognize the character.

Conclusions

Based on isovist idea, this paper developed a new method SSOD (Street space outline diagram) mapping the urban space. This method collects the data of urban street skylines based on a viewpoint. The data include three parameters of each point on the skyline. They are the horizontal angle " α ", the elevation angle " θ ", and the distance " d ". All the data are stored in MATLAB, and can be calculated. In this paper, we draw a diagram of the elevation angle and the distance change based on the horizontal angle change, which can show the characteristics of different street patterns.

Different from previous isovist method, this method includes the third dimension of urban space, and all the data is accurate and can be calculated. Teller's (2003) method is three dimensional, but it is not so accurate, and the mapping result can not restore to the original space. Fisher-Gewirtzman's (2005) method only collected one parameter of the space that is 'spatial openness index' (SOI). Ratti (2004) created the raster analysis of urban form which can show the third dimensional data of space. But the raster image does not have precise data, too. In SSOD, all the data of space is stored in MATLAB. We can find the exact data of any point of the skyline, and the data can be restored to the original space if we want. The accurate data can be used to analyze the rules between diagram and real space, or the relationship between the parameters.

But there are still some difficulties in further study. For example, it is easy to recognize the characteristics of the diagram of simple pattern of street, but when the pattern become complex, it may be difficult to identify the character in the lines of the diagram.

Our further work may focus on the issue that how to analyze complex street pattern using SSOD. Another interesting issue is to find more information in the data such as the relationship between parameters.

Changing form of the Baltic cities: resurrection of the suburbs

Matas Cirtautas

Urban Research Laboratory, Department of Urban Design, Vilnius Gediminas Technical University, Pylimo 26/1, Vilnius, Lithuania, E-mail: archimatas@yahoo.com

Abstract. *Urban sprawl is one of the dominant types of urban development in advanced and developing world (Bruegmann, 2005; Clapson and Hutchison, 2010). It is described as a process of gradual conversion of rural areas into partly urbanized environment. Although outer growth started from the outset of cities (Mumford, 1968), international community of urban researchers, planners and policy makers is highly concerned about the current extent of this phenomenon (EEA, 2006). Extensive urban growth is often considered as uncoordinated process creating fragmented suburban landscape (Sieverts, 2003; Meeus and Gulink, 2008), which is frequently associated with an increased traffic flows, environmental pollution, inefficient use of public funds and formation of homogeneous living environment (Couch, Leontidou and Petschel-Held, 2007). Current development of the Baltic cities and especially trends of their suburban growth have been analyzed only partly, because of the relative novelty of the phenomenon and well-established dominance of North American cities in this field. The article attempts to fill this gap and present a research on conditions and consequences of extensive development of major cities in the Baltic States. This study is based on a hypothetical model of the Baltic city as successor of the Soviet city in the Baltic region. Evidences from the recent growth of Lithuanian cities show that suburban sprawl is a dominant trend in major urban regions with long-term consequences on their spatial structure (Cirtautas, 2013). Therefore, this article advocates a need to revise urban policy in the Baltic countries and promote coordinated development of urban, suburban and rural areas in the context of prevailing negative demographic trends and limited economic capacity of both, central and local governments.*

Key Words: Urban sprawl, suburban development, post-Soviet city, Baltic States.

Introduction

Over the last century cities in the Baltic States have experienced several fundamental transformations of their urban form. From historical compact towns they became large cities with distinct characteristics of late Soviet era. Although maintaining some weaknesses (disparities of population concentration, low quality housing, monofunctional land use, transport infrastructure unintended for mass usage of cars, etc.), these cities had rather completed polycentric structure of scattered residential, institutional and industrial complexes. This physical and functional layout was based on multi-level system of services and has provided urban population with basic amenities for living, working and recreation (Šešelgis, 1970). In recent decades, Baltic cities, as all post-socialist cities in Central and Eastern Europe, have been exposed to multiple transformations (Milerius, Tornau and Dranseika, 2009). This encourages researchers to pay more attention to processes which are shaping urban areas in these countries.

Studies of current development of the Baltic cities frequently involve description of suburban areas. However, evaluation of emerging semi-urbanized landscape is often limited to a simplified interpretation of the phenomenon, based on experience from the Western countries. Usage of untenable arguments prevents closer investigation of exclusive characteristics and targeted solutions for problem solving in these urban regions. Therefore, the article examines changes around major Lithuanian cities assuming that gained morphological knowledge can upgrade urban planning and design principles for suburban areas.

The study covers analysis of centrally collected statistical (demography and housing) and geographical (land cover) data with detailed analysis of urban structure of settlements. This helps to identify zones of intensive suburban development and establish a link between

development processes (as condition) and the prevailing form of the suburban settlement (as consequence). Giving the scale of the suburban growth and the negative demographic trends in the Baltic States, current development of suburban zones in long-term can lead to environmental deterioration and social decline of central cities. Therefore, investigation and monitoring the development of these areas are necessary. The study does not try to be a comprehensive work on external growth of the Baltic cities. However, it presents a wide range of challenges of urban sprawl in the region and highlights possibilities for further and more detailed research of the phenomenon.

Characteristics of the Baltic city

Historical development of the Baltic city

Baltic States – Lithuania, Latvia and Estonia – are located on the eastern coast of the Baltic Sea. Because of the specific geopolitical situation urban development in this region for a long time has been exposed to cultural influence of both, Western and Eastern Europe. However, during the 20th century, when growth of cities reached the peak, the Baltic countries were directly influenced by communist urban development. Therefore, local urban landscapes are perpetuated with physical and ideological signs of that period. Separate urban development of the Baltic countries took place during the interwar period (1918-1940) and has continued after the restoration of independence (since 1990), in the course of European integration and globalization processes. The latter marks accelerated social and economic transformations in the broader space of post-Soviet Central and Eastern European countries (Stanilov, 2007). Some of the changes in action were planned and carefully guided, while others – including urban development – took place under self-regulation of free market.

Transformation processes which took place in the Central and Eastern Europe after 1990 influenced changes in spatial structure of the Baltic cities. During the second half of the 20th century urban development of the Baltic countries was mostly related to the concept of the Soviet city, which, according to some authors, significantly differs from cities in the capitalist world (Hirt, 2006; Burneika, 2008). In a physical sense, the city of late Soviet period was characterized by two fundamentally different morphological zones: the historic centre and large housing estates on the periphery, supplemented by industrial and institutional complexes. The main difference from Western analogues was that Soviet city did not possess a suburban ring of low density residential constructions. This distinct feature was determined by the centralized urban and regional planning system of the Soviet period, which promoted specialization of large industry as a base for development of urban networks and encouraged construction of unified and standardized housing within cities.

According to a simplified view, morphological evolution of the Baltic cities can be divided into three major phases: pre-Soviet (till 1945), Soviet (1945-1990) and post-Soviet (since 1990). This division is very general, yet it represents essential differences in the principles of town planning.

The pre-Soviet period covers a long time span – from the emergence of the states till the end of World War II. It also manifests very different socio-cultural conditions of urban development, e.g. from medieval feudalism to democracy in the interwar period. However, during this phase towns were relatively small and compact. The Baltic countries at that time were still dominated by rural population. Towns in this period usually were multicultural settlements, which acted as centres of trade, defence and administration (Miškinis, 1991).

During the post-war period cultural and social landscape of the Baltic States changed dramatically. Concentration of industry in the major cities and large inflows of population stimulated their growth. Regarding the pace of urban expansion and dominant construction principles, urban development in the Soviet period can be divided into early (1945-1960) and late (1970-1990) stages (Ramanauskas, 2011).

In the early stage, continuing the traditions of interwar period, urban areas were planned by quarters, but they were build-up already with new types of buildings, which represented architectural style of “socialist realism”. Later, after the adoption of common guidelines for urbanization of the Baltic countries (in Lithuania regional planning scheme was issued in 1964) and introduction of new standardized technologies for residential, public and industrial constructions, cities started to grow mechanically. Due to the absence of private property, there were no restrictions on location and scale of new developments in the Soviet city (Bertaud and Renaud, 1995). At the same time ideas of urban and architectural heritage preservation started to spread among local architects and urban planners (Jurkštas, 1994), so they tried to enrich projects of new buildings with features of national identity. However, poor quality of construction materials and works limited these attempts to just design of architectural details or more contextual layouts of free standing buildings. Nevertheless, the overall picture of new parts of the cities was gaunt and, with small exceptions, similar to other cities in the Soviet Bloc.

After political changes in 1990, the urban development of the Baltic countries has abandoned the former course. Although the polycentric urban systems, which more or less have been developed during the Soviet period in the Baltic States, are identical to the conception of decentralized concentration (Daunora, 2007), further centrally governed development of major urban centres became impossible (Juškevičius and Valeika, 2007). Thus, previously centrally planned cities had to adapt to a completely different political and economic situation. Land privatization, decentralization of governance and competition at the national and global levels were essential features of this new reality. The further development of physical structure of the Baltic cities was also affected by economic restructuring, deindustrialization, negative demographic trends, traffic problems and, of course, the lack of planning standards for controlling land-use development processes in cities and around them (Nuisl and Rink, 2005). All this has led to the strengthening of private and commercial interest in the urban development processes (Juškevičius and Vitkauskas, 2001). Therefore, recently the Baltic cities, as all post-socialist cities in Central and Eastern Europe have experienced intense commercialization of central parts and suburbanization of their peripheries (Sýkora and Ouředníček, 2007).

Current form of the Baltic city

Current form of the post-Soviet city is frequently conceptualized as consisting of three rings (Sýkora, 1999; Hirt, 2006), which represent central, middle and peripheral zones. These zones correspond with historical stages of growth and serve as a basis for evaluating current urban transformations. Since the Baltic cities had mostly expanded during the second half of the 20th century they have also inherited this particular structure.

According to the example of Lithuanian cities (Figure 1), the central part is a result of city's organic growth till the middle of the 20th century. It spans throughout an old town and other historical neighbourhoods (new town with rectangular street pattern, historical quarters of villas, etc.). The second half of the 20th century in the Soviet city was dominated by the construction of large housing estates which form the middle part of the Baltic city. This area also includes industrial and specialized complexes (hospitals, universities, etc.) with large forest parks and other open green spaces situated in between. Suburban periphery is often referred to as the most recent zone of the post-Soviet city (Burneika, 2008). Its physical fabric is framed by historical homesteads and villages, garden communities, quarters of single-family housing, highways, modern warehouses and recreational complexes. There are also many fragments of former agrarian and natural landscape, which formerly dominated throughout the suburbia.

Figure 1. Development model (A) and current form (B) of the Baltic city.

Currently the Baltic cities face three major challenges which will determine their future form: regeneration of central parts, modernization of large housing estates and development of emerging suburban zones. The first two subjects are frequently discussed in the political and professional field (Aistratovaitė, 2004; Džervus, 2013). Although urban sprawl is recognized as the predominant type of urban development (Cirtautas, 2013), suburban structures are still poorly investigated because of their relative newness and complex form.

Research of urban sprawl around the Baltic city

The main question asked in the research was, what shape the suburbs of the major Lithuanian cities do acquire in the context of active socio-demographic, cultural and economic transformations in the Baltic States? Referring to the previously presented characteristics of the Baltic cities, suburban areas can be described as one of the most dynamic parts of these cities. Therefore, the current phase of urban development in the Baltic countries can be partly described as resurrection of the suburbs. Growing demand for better housing has increased importance of peripheral parts of the Baltic cities. Although, development of these areas is an antithesis of sustainable urban growth, there is a need to find ways and means for evaluating strengths and weaknesses of suburbs and discussing their future development scenarios. In this case significance of morphological knowledge needs to be acknowledged as it is obvious that urban environment with well-established social structure and more or less traditional urban form should be a prior objective while regenerating the existing and planning new suburban settlements.

Phases of the research

Suburban areas are often analyzed indistinguishably from the metropolitan region which they belong to. However, researchers are often faced with the problem of availability of information, when studying urban forms at such great scales (Talen, 2003; Clifton et al. 2008). Since urban sprawl studies examine large areas, it is convenient to split research process according to monitored data sets and their accuracy. Research of extensive growth of major Lithuanian cities was divided into two phases. Firstly, the analysis of centrally collected data on socio-demographic trends, changes of housing structure and land cover has been performed, which helped to draw preliminary conclusions about development conditions in preselected suburban areas. Later, this was followed by detailed analysis of physical characteristics of suburban settlements.

Data sets and their accuracy

During the first phase of research, information of two recent population and housing censuses has been used. The data set of 2001 consisted of 77 indicators aggregated for smallest administrative units – settlements. The second data set included 36 indicators generalized for cells of 1 km² and representing development conditions in 2011. Both sets of statistical information cover all populated areas of the Republic of Lithuania. Although different in their content and accuracy, information in these data sets represents conditions of socio-demographic and (partly) physical transformations in Lithuania after 1990.

Trends of land cover changes were analyzed by using national data sets of Corine land cover data sets of 1995, 2000 and 2006. Corine land cover data is widely applied to study urban sprawl around European cities (Vaitkus, 2005). This is done by rendering extend and change of urban morphological zone, which is defined as a set of urban areas laying less than 200 meters apart (EEA, 2010). Typical procedure of identification of urban morphological zones has been slightly adjusted, adapting it to the case of Lithuanian cities. Changes of individual types of land cover were analyzed in accordance with similar studies performed by other researchers (Chuman and Romportl, 2008). Results were generalized to represent rate of land cover change as percentage of the total area in a particular cell of 1 km².

Transformations of suburban settlements were analyzed using georeferential data, representing urbanized areas, buildings, road network and other major physical elements. The extent of growth of built-up areas was adjusted according to the orthophotographic material of respective year (1995-2001 and 2012-2013). In this stage additional investigation of the register of territorial planning documents has been performed as well.

Although the study included examination of different data, the illustrations presented in this article were prepared at the same scale. The aim was to demonstrate the relationship between development processes and physical changes in suburban communities.

Research cases

Suburban development trends around major Lithuanian cities (Vilnius, Kaunas and Klaipėda) are demonstrated through description of situation in three local administrative units of 2nd level (LAU2, former NUTS5). Suburban sprawl led by influence of Vilnius city is analyzed by examining demographic and physical transformations in the community of Avižieniai. Changes around Kaunas are analyzed in the community of Ringaudai. The community of Sendvaris illustrates drastic consequences of uncoordinated urban expansion just outside the city of Klaipėda (Figure 2). All communities represent politically autonomous territorial units – they are parts of rural municipalities, which surround major cities. These communities are directly exposed to economic and functional influences of adjacent urban centres, because they are located at about 5-15 km from the city centres.

Figure 2. Case studies – suburban communities of major Lithuanian cities.

Conditions and consequences of suburban change around Lithuanian cities

Trends of demographic change (population size and density)

Suburban communities which were examined in the research, belong to areas with highest residential growth in their municipalities. In 2011 Ringaudai and Sendvaris had up to 5000 residents, and Avižieniai – more than 7500. Over the last decade population in these areas increased from 40 to 90 percent. During this period, structure of settlements has remained quite diverse with just few settlements reaching more than 500 residents (Figure 3). However, changes also occurred in less populated places – increased number of settlements with population over 200 residents has been noticed as well.

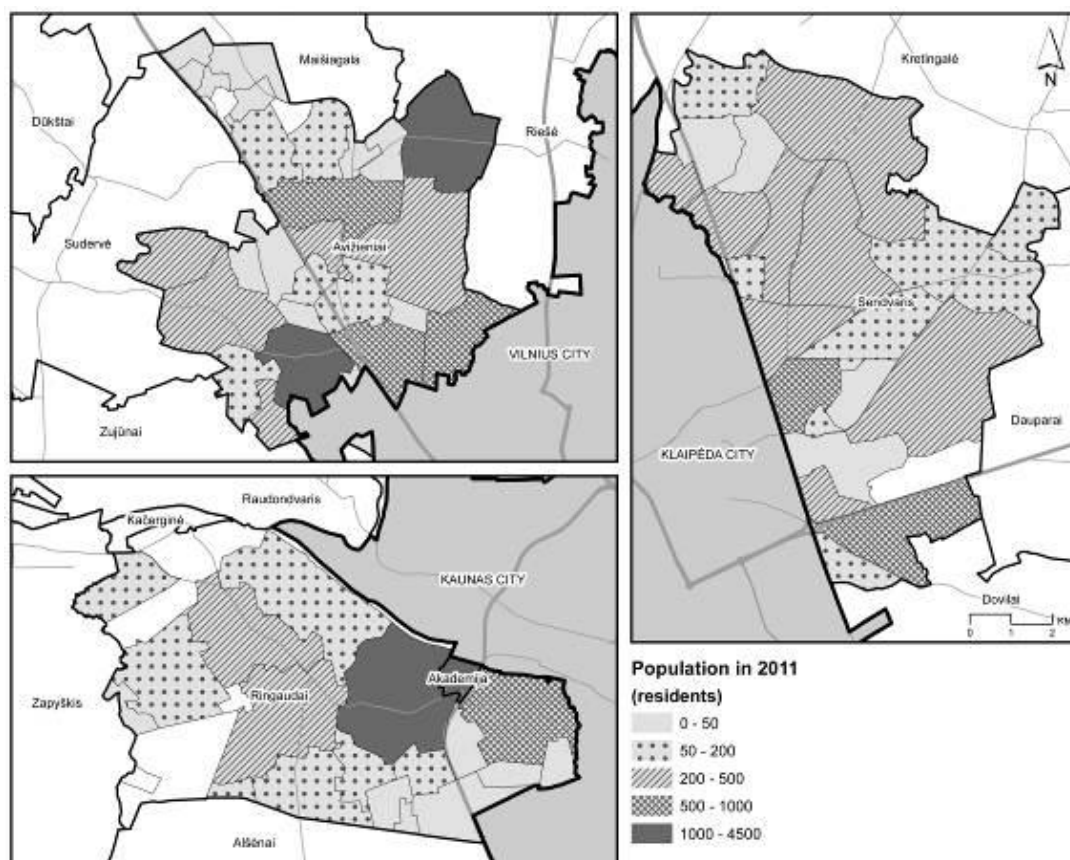

Figure 3. Population in the suburban communities in 2011.

Unfortunately, population density in the suburban communities remained low – in 2011 outside larger settlements it has not reached two persons per hectare. Population density in built-up areas showed higher rates, but rarely reaches five persons per hectare. During the last decade in some parts of Ringaudai and Sendvaris this ratio even declined. This suggests that in some locations due to higher land prices residential areas are more compact. This might also be caused by the fact that part of new suburbanities had not officially declared a change of their residence.

Changes of housing structure (single-family housing)

According to the traditional suburban image, it should be dominated by single-family houses. Already in 2001, the communities in question showed high share of low density housing, which accounted for 50 or more percent of all dwellings. One-fourth of these were built after 1990. During the Soviet period low density housing was forbidden in large cities, therefore in 2001 this type of dwellings accounted just about 10 percent in Vilnius and Klaipėda, and only in Kaunas ratio was higher (10 to 30 percent). However, significant part of single-family housing in central cities was constructed during the first decade of independence, with higher numbers registered in Klaipėda (up to 50 percent). This trend could be influenced by incorporation of rural areas into the cities. On the other hand, new blocks of detached houses have been built inside cities as well.

In 2001 detached houses dominated in major part of settlements in Avižieniai and Ringaudai (Figure 4). Only in larger settlements and areas near the city border it was lower than 70 percent. A smaller amount of individual housing can be attributed to higher ratio of dwellings in low-rise block of flats. Apparently, similar reasons, determined the housing structure in the community of Sendvaris near Klaipėda. Here in 2001, detached houses dominated only in several older or newly emerging settlements. However, data from 2011 shows that individual dwelling dominated in almost all parts of the analysed communities. This suggests that ongoing expansion of the major cities in Lithuania is mainly associated with construction of single-family housing.

The analysis of the structure of residential buildings in the suburban communities shows, that during the first decade of independence it became more diverse, but generally still was dominated by buildings of the Soviet period. In 2001 settlements in Avižieniai were dominated by the buildings of 1946-1970. However, in areas located closer to the city limits, higher numbers of residential buildings of later periods have been noticed. The same trends are specific for settlements in Ringaudai and Sendvaris, but here significant share of pre-soviet buildings has existed.

It is likely that considerable part of construction works in the suburban areas after the 1990 consisted of upgrading the existing building stock in order to meet the changing needs of households and businesses. However, data sets of the population and housing censuses do not possess this information. Therefore, these trends can be observed only on a very detailed level of analysis.

Trends of land cover change (residential and commercial sprawl)

The analysis of expansion of urban morphological zones around the major Lithuanian cities in 1995-2006 shows, that at first growth of built-up areas progressed inside the cities or in places located near their administrative boundaries, but later outer expansion embraced large portions of suburban areas. In this case, the community of Avižieniai with adjoining territories became part of north-west development axis of Vilnius city. Sendvaris started to represent the eastern sector of urban expansion in Klaipėda region. These areas were gradually affected by processes of suburban sprawl. Despite lesser extend of urban sprawl in the community of Ringaudai, Kaunas city still experienced high degree of uncoordinated outer growth.

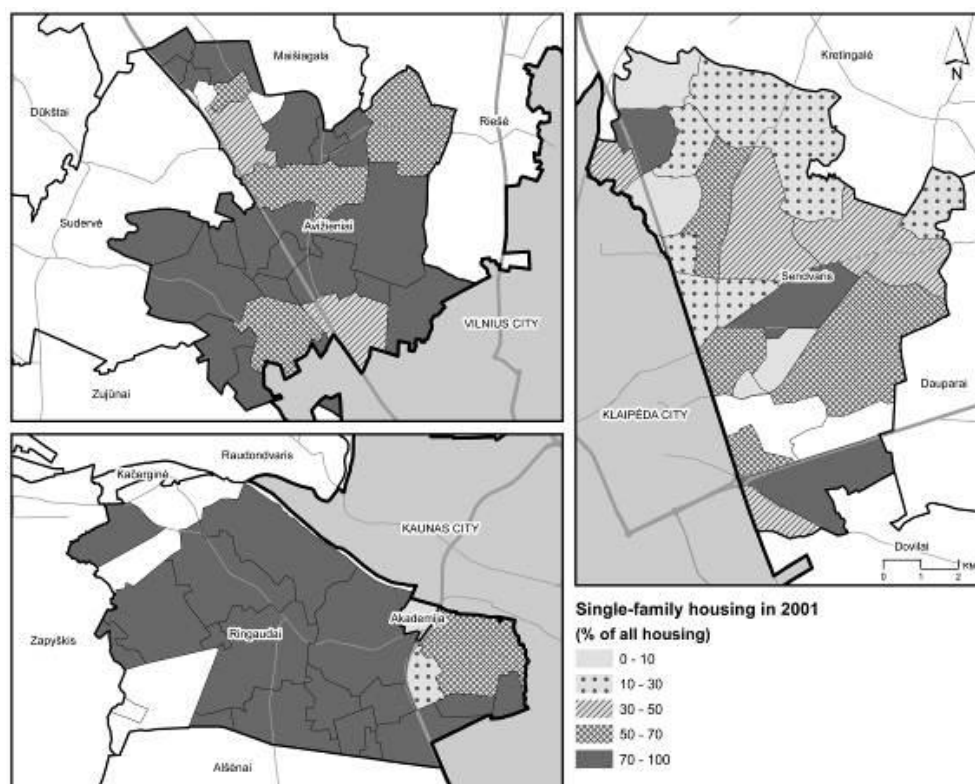

Figure 4. Single-family housing in the suburban communities in 2001.

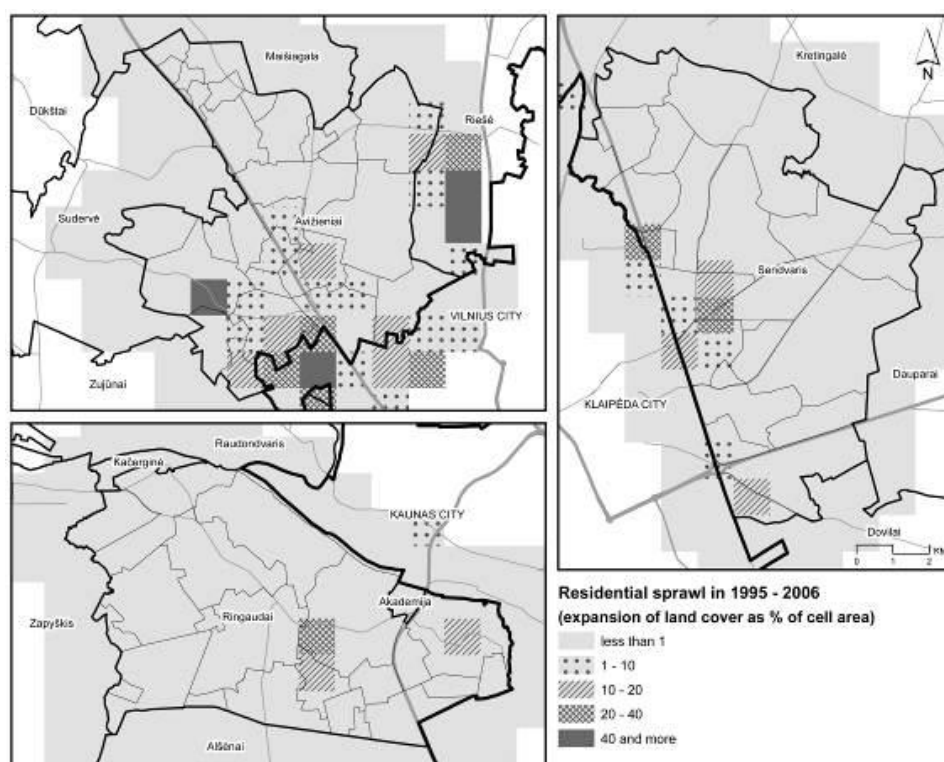

Figure 5. Residential sprawl in the suburban communities during 1995-2006.

Urban sprawl is a heterogeneous phenomenon. It consists of growth of residential, commercial and infrastructural areas. Although these processes represent distinct functional domains of the urban landscape and usually operate at the same time, their spatial patterns can diverge. The comparison of different processes of land cover changes reveals that majority of alterations can be attributed to residential sprawl. The case of Avižieniai is exceptional. Here growth of residential areas was quite intensive and affected settlements adjacent to Vilnius city and also in some remote locations (Figure 5). In Ringaudai residential sprawl was observed in several locations around larger rural settlements. In case of Sendvaris, this type of urban sprawl dominated in settlements neighbouring Klaipėda city. In general, the growth of residential areas around Lithuanian cities is characterized by both nuclear and dispersed patterns. During 1995-2006 territorial expansion of commercial and industrial areas also featured some degree of concentration, however it was insignificant. In most cases, this type of development occurred near highways leading to the cities or appeared in the vicinity of major transport nodes.

Concentration or dispersion of land cover transformations reveals disparities of urban development. However, the pattern of urban sprawl depends on spatial structure of metropolitan and (road network, natural constraint, etc.) local scale (land-use, land ownership, etc.) Residential and commercial sprawl usually take place as a greenfield development and drastically changes the landscape of suburban areas. Therefore it is necessary to examine physical features of emerging suburban settlements.

Physical transformations of suburban settlements

As the review of development conditions in the suburban areas of major Lithuanian cities has shown, external growth of urban areas is quite noticeable, especially after 2000. Therefore, we can observe formation of the suburban landscape, which is characterized by mosaic of urban, agricultural and natural areas. Fragmented urban fabric in peripheral zones can be described and analyzed using basic elements of urban fabric: buildings, streets and plots (Levy, 1999).

The higher or lower pressure on urban development can be noticed in various places of the wider space of the suburbia. According to their distance from the central city, three types of suburban settlements can be identified: 1) residential areas on the periphery of city, 2) residential areas located immediately behind the administrative boundary of city and 3) self-sufficient suburban settlements. However, development pressure can also be visible at more distant locations of metropolitan region, e.g. periphery of the remote towns and large villages. Similarly, there are other specific types of semi-residential environment, which can be affected or even created in the course of suburban sprawl, e.g. garden communities and areas of seasonal or second housing. Respectively, communities in question are dominated by the second and third type of suburban settlements, which represent former villages and newly emerging areas of low density housing.

Comparing patterns of built-up areas in the suburban communities near major Lithuanian cities in 2001 and 2013, high increase of new constructions is visible (Figure 6). These new developments usually appear near the older settlements or occupy former agricultural fields. In many cases, it is evident that new suburban residential structures favour locations in the vicinity of major transport corridors and natural features. However, residential areas expand in a very chaotic way and usually leave large fragments of undeveloped land in between. New settlements could acquire more regular urban form, but as long as these speculative voids prevail, suburban areas will remain incomplete and fragmented.

During the last decade, formation of new low density housing blocks and expansion of older rural settlements in the communities of Avižieniai, Ringaudai and Sendvaris can be noticed. In the case of Avižieniai, new residential structures were built across the border of Vilnius city, so that adjoining urban and suburban fabric started to merge. Construction within built-up areas was not common, but occurred in all communities.

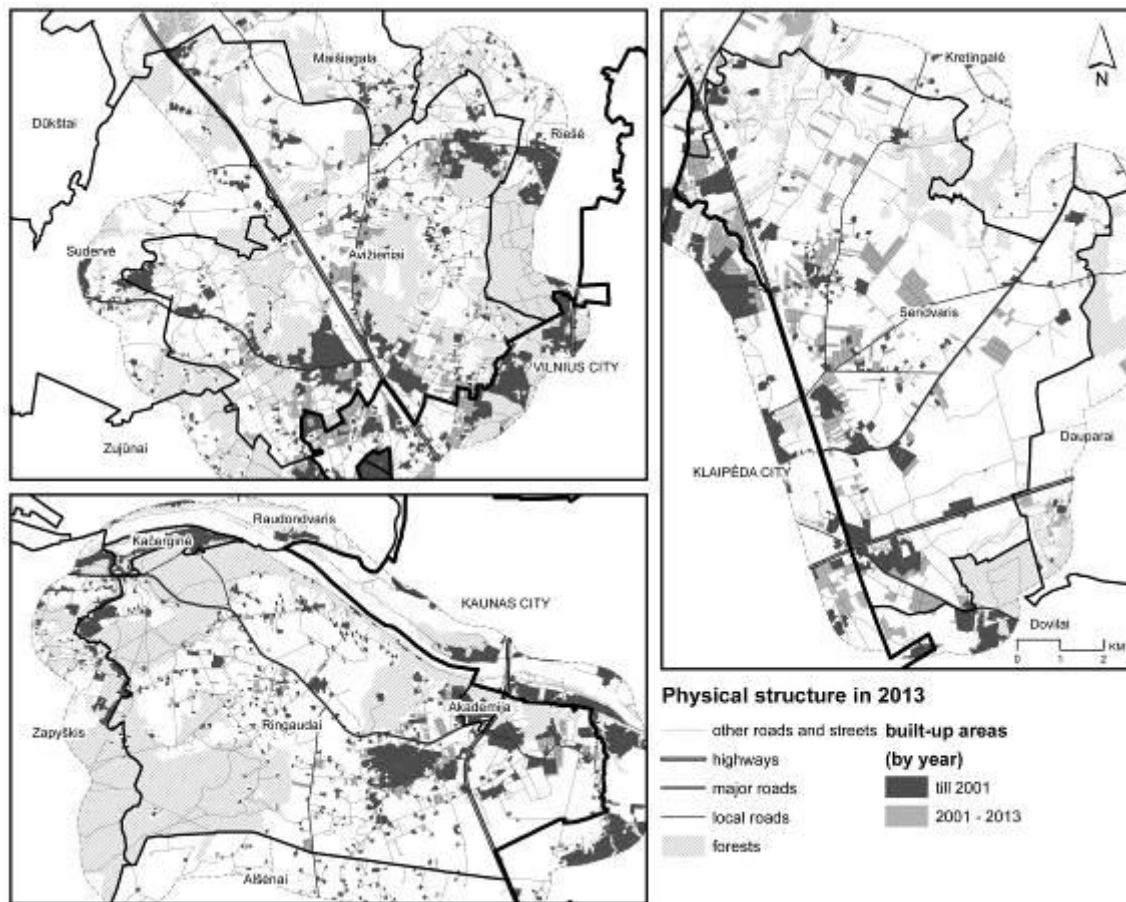

Figure 6. Physical structure of the suburban communities in 2013.

In general, all new residential formations can be divided into several morphological types. According to their relationship with the pre-existing suburban fabric, they represent infill, extending and outlying structures (Figure 7). The infill structures are usually small in size and appear on previously undeveloped land, which is fully or partly surrounded by built-up areas.

Extending structures usually border and expand older residential areas. This type of suburban tissue can be subdivided into regular and linear formations. Regular structures are formed mostly by extending pre-existing street grid of settlement, while linear structures form around separate cul-de-sacs. In some cases, small enclosed residential structures create leapfrogging patterns, which incorporate former homesteads or even small rural settlements. Such extensive and complex formations could be considered as additional subtype of extending suburban structures.

When new residential constructions appear in locations, which are relatively distant from current settlements (for example, more than 200 meters), they can be considered as outlying structures. These greenfield developments can acquire various spatial configurations and greatly differ in size, because usually they are separately planned and relatively instantly built on any undeveloped land.

There is also a trend to construct single residential structures on large plots of agricultural land. It partly reminds the dispersed pattern of historical farmsteads, which is considered as valuable element of rural landscape of the beginning of 20th century (Ramanauskas, 2011). However, currently emerging single residential structures are just another example of suburban housing.

To sum up, the infill and extending structures can be considered as more traditional than outlying formations, which are typical for intensive suburban development of the Western

countries during the 20th century. In reality, these morphological types are not so easy to distinguish. The main reason for this is the dynamic nature of suburban development, which is characterized by the time lag between planning and construction works. The analysis of land-ownership structure suggests that the amount of pre-planned plots for residential construction in the suburban communities is impressive. For example, in the community of Sendvaris, which is located near Klaipėda, supply of residential plots is high enough to house ten times more new residents than this community has received during the last decade. Therefore, it can be said that currently the prior direction of urban development in Lithuania is suburbanization. However, spatial and functional structure of suburban settlements still does not meet standards of high quality residential environment.

Figure 7. Fragments of emerging suburban fabric: extending (A), infill (B) and outlying (C and D) structures.

Conclusions and discussion

The model of the Baltic city, as successor of the Soviet city, can be used to study trends of urban development in the Baltic States after 1990. This model consists of three concentric zones, which reflect different stages of city's growth and helps to describe distinct morphological features of urban form. In recent decades, periphery of the Baltic city experienced significant transformation, therefore latest phase of its development can be describes as resurrection of the suburbs.

As stated in the article, intensive development of suburban areas around major cities in the Baltic countries is problematic phenomenon. First of all, the process is politically uncoordinated (especially at municipal level), and secondly – it is not based on any demographic presumptions. This leads to the situation, where all more or less negative effects of urban sprawl can occur, e.g. decline of central cities, inefficient use of suburban areas and so on.

From a morphological point of view, suburban growth is complicated as well. The main problem is that resulting semi-urban structures acquire chaotic and fragmented shape. For example, peripheries of the Baltic cities is dominated by large patches of greenery and opens semi-natural spaces, dispersed pattern of former rural settlements and newly constructed low density commercial and residential areas. And all this is superimposed by the networks of major and local roads. Nevertheless, tools of morphological research can be adapted to study contemporary suburban fabric around the Baltic cities, as it has been done in other counties (Southworth and Owens, 1993; Moudon, 1998; Sheer, 2001). This allows identifying regional characteristics of suburban form, which can be useful considering possible development scenarios for territories adjacent to major urban centres.

In general, major cities in the Baltic States represent examples of semi-compact cities evolving towards a dispersed urban form. Regarding this, three scenarios for their future development can be discussed. The first scenario – further expansion and urban dispersal – represents continuation of urban sprawl with all possible negative outcomes. The second scenario – fragmented regeneration and densification – stresses the possibility to apply area based measures for renewal and regeneration of pre-selected inner city zones, as well as densification of progressive settlements on the periphery in order to concentrate financial capacity of national and local government to deal with problems in these urban and suburban areas. Finally, the third scenario – urban renewal and reurbanization – enables the application of compact growth measures to strengthen existing urban cores of metropolitan regions, but it can only proceed as agreement between representatives of urban and adjoining suburban municipalities, because it requires political means to restrict or at least discourage processes of uncoordinated outer growth.

Overall, it is necessary to continue promoting public concern and share information about negative consequences of urban sprawl and discuss possible measures to sustain a more compact form of cities in the Baltic region. Therefore, results of this study could be adapted to further examination of the identity of the Baltic cities as well as comparing its historical evolution with cities in other regions of the world. Also, there is a great need to continue research on the current trends of urban transformation in the Baltic States in order to create models designated to coordinate further development of major cities and their suburban regions. And finally, it is crucial to perform closer morphological analysis of emerging suburban fabric and distinguish origins, physical characteristics and transformation possibilities of different settlements.

Mind the gap. Multi-scale landscape approaches

Francesco Marras

DICAAR- University of Cagliari, Via Santa Croce 58, Cagliari, Italy

E-mail: francesco.marras@unica.it

Abstract. *The expression “mind the gap” refers to the act of paying attention to crossing pass from one element to another. In urban transformation and architecture project it is necessary to reflect on the concept of distance and crossing in particular in relation to the theme of the change of scale and especially from urban design to the architectural design and detailed design. The method is based on a deep morphological analysis of the territory and the landscape and detections of elements and invariants inside, after establishing the invariants you are able to define a formal grid that keeps continuing at all scales of design, starting the territorial scale up to reach the scale of architectural detail. Supporting this reflection may present a set of projects that participated in the competition European 12 which show that the multi-scale approach can be a way to control an urban transformation. The project at multiple scales can be a basis to monitor and study the existing urban form and to reflect on the possibilities of future transformations going to define development scenarios and guidelines for the territories.*

Key Words: *Multi-scale, urban morphology, geography, urban project, landscape.*

Introduction

Mind the gap represents a sign of the world-famous London Underground, it is a warning to pay attention to the distance between this platform and the train. This research aims to reflect about this warning to pay attention to the distance in terms of the intervention scale in landscape design, and architecture of the city. So *mind the gap* becomes the categorical imperative of an approach method of city design through a multi-scale system that crosses all scales. This can be a useful support system in decision-making and design, through the reconsideration of technical, thematic and relational characters of the project. The idea came from the need to find a binder between the various stages of project linking the analysis on territory than on detail. We start therefore with a strong multidisciplinary system that goes from historical and economic to the morphological, hydrographical and environmental point of view, until the scale of the object that can be a building retail or a piece of furniture; the idea is precisely to find a *fil-rouge* that addresses all scales and in particular supports the thesis of the project's consistency and its relationship with the place. The issue, therefore, is a part of landscape architecture strongly directed towards the project.

Scale adherence

The scale is a need for understanding, but not a principle in itself. So, it follows from the principle of relative invariance of a system "all organic", in relation to the increased variability of its components. The consequent organization in space-time depends on the irreversibility of time, which leads to a sequence of scalar processes, because the flow of time is not homogeneous (Ingegnoli, 2000). In fact, if the processes are thought of as "verbs", in other words the potential becoming of a subject, for example: moving, dispersing, evolving, and many others. The working out of a process is scale-dependent, while the process itself is invariant under the scale (Sanderson and Harris, 2000).

The theme of scale adherence is crucial in the design of architecture and landscape design, in particular with the possibility to identify a link between territory and architectural object, and above all between place, landscape and architecture.

Roberto Gambino talks about scaling-up, referring to those processes and techniques of analysis and plan that are based on multi-scalar and multi-temporal approaches, extending the reference system to the 4-dimensions. In this regard the analysis of scaling-up follows an inductive approach that deals with the themes of the regional scale to arrive to the urban scale, across the various scales of analysis arise various problems that often fall into the dichotomy of global/local and with the changing identities of contemporary territories (Gambino, 1997). These are the so-called *in-between* spaces. In these fields indefinite contemporary design is tasked to act, to produce its rhizomes and create a network of relationships with the existing one (Farina, 2006).

Gambino talks about multiscalarity as a need that must be set as a matter of fundamental programmatic planning going to define the issues related to the "territory of the inhabitants" (Magnaghi, 2000). The School of the Polytechnic of Bari talks about cross-scaling, as a comparison of the change, the transfer and adaptation of models of ecological analysis to the landscape scale respecting the levels of hierarchical organization (King, 1991), from whose cartographic document scale and survey data were dictated by historical and cultural contingencies. Mariavaleria Mininni shifts the focus on the knowledge construction in landscape theme that is a fundamental cornerstone of the European Landscape Convention (Mininni, 1999).

Knowledge becomes the first step to approach the theme of landscape design, both for the formulation of choices, both for the involvement of the players whose activities affect landscape. This makes it possible to identify the components of the landscape within the territory, analyze their characteristics and modification tensions. The different texts and different practices already in progress reveal a wide variety of approaches to the topic that are a reflection of the many cultural conceptions that are compared, especially in the relationship between the construction of knowledge and action, in which the available tools are often inadequate. Landscape in fact demands answers in different scales ranging from the local scale to that of the particular crossing different time scales.

Landscape knowledge should be developed according to a process of identification, characterization and qualification which includes the description and understanding of the places, the examination of evolutionary processes and the recognition of the value systems. In this regard it may be interesting to draw cards, atlases, manuals and other useful tools primarily to provide a reference and a common language in order to increase the dialogue between the interested parties. The construction of knowledge must be closely linked to the action in order to facilitate the integration of different approaches to the production of knowledge that allow to observe the region through the construction of databases and other tools that are able to draw the traces on the territory. This is the work that follows the know, in other words that of the interpretation, and evaluation of reading that precedes action. In this regard, Bernardo Secchi says, "Planning means the traces of a wide set of tracks, those of the continuous and conscious changing of territory and city status" (Secchi, 2007).

The method

The multi-scalar approach is a method of reading heavily project-oriented and in particular through the analysis must be able to address different scales of the project, therefore, constitute the corpus of surveys which are actually "already project". In this way, through this system of guidelines the project may have a strong element on which to support themselves and with which to generate a system of relations: the *rhizome* (Deleuze and Guattari, 1987). The support of the rhizomatic structure consists of a series of synchronic and diachronic investigations aimed at identifying the invariants that govern the landscape. The analysis assumes that landscape is the object of the search and goes to determine the structural basis. Eugenio Turri talks about *iconemi* about some elements which he defines as basic units of perception (Turri, 1974). The sum of these elements and their combination form the overall image of the country,

rising primary elements such as structuring the historical and cultural memory of the place. The evaluation and selection of invariant and *iconemi* forms the basis of multi-scalar system, in other words the elements on which the multi-scalar approach can be found and that can be explored at different scales and made system with the project. The identification of invariants and *iconemi* is based on a series of overlapping layers: morphology; hydrography; infrastructure; settlement; agrarian plot.

It should be interesting to put together physical readings with other ones that are based more on a historical study and photography, considering a system consisting of historical and current photos with different field of view degrees, from panoramic photos to the detail. Reflecting about diachronic analysis it is necessary to support the research with the cartographic archive aims to assess any items that do not emerge from eminently morphology. The attempt is to build the readings that go beyond the eminent morphological data and beyond the historical, cultural and perceptual one.

The reflection on the scale is aimed at the identification of invariant to the regional scale and then the exploration of these three basic steps type, or the territory scale and the environmental system, the urban scale and urban form, and the scale of the neighborhood or the city block or in some cases until the architecture and construction detail. Such a descent of scale is based on a reading of territorial planning and well targeted on the lens that filters the information coming from the territory in order to define its own character. Reflecting on the concept of landscape emerged from the European Landscape Convention and then the translation from aesthetic landscape and operating landscape on what Eugenio Turri talks about landscape "A landscape is in fact dimensionally defined mostly by its content; is its content, which determines the size, which also depend on our attitude, subjective, interpretive, in which we merge our experience of the world (aesthetic, emotional, cognitive, etc...) that leads spontaneously to recognize the landscape" (Turri, 1974).

The sign reading "makes landscape" and outlines the main characters of the place, the project has the task of interpreting the signs of the area and take a critical and judgment with respect to them. In this way the reading of the territory becomes an opportunity for the emergence of values and important data at different scales that are stakeholders of territorial scale. The interaction between paper and photo contribution is essential at different scales and may highlight the continuity and the reading of the invariants in the steps of landscape scale. So the search proceeds from the territorial scale to the urban scale where the focus shifts on the definition of the relationship between urban form and environmental dominant and how these have changed, modified and mutated the settlement. The choice of the invariant rules and defines this scale and a reading mode that explains how the latter is put in the scheme with the whole system (Figure 1).

Figure 1. Network thickness.

The mutual relationship between the parties will then have its keystone in the project, closing arguments and defines the multi-scalar and complete them at the same time deeply rooted with

them and therefore with the place and with landscape. The further descent of scale can go to the scale of city block where the invariants often are reflected in the elements, lines or points that become references, limits or areas in which the project is to *feed* the relationships of mutual exchange and reciprocal relationship. If the landscape is the language of the land, we need to investigate not so much the “syntactic structure”, which represents the most objectified and uniquely quantifiable (ex: in terms of natural resources and material values) as the recognition process, in other words a process of identification that binds all communities within its territory “producing” valuable landscapes. Starting from the signs and landscape invariants, it is therefore possible to retrace the shared construction process that belongs to landscape, as well as giving new meaning in those contexts that express different resources today than in the past. The project is proposed as a multi-scale design for a landscape that is now sprawling, the concept of which often escapes to the treatise. The multi-scale flow allows to give clarity to the project, the hierarchy between the parties and *getting roughs* into the place. Arjun Apadurai talks about “production places” like the activation of a particular place and the person's ability to change and to transform it (Tosco, 2011).

Applications

The multi-scalar approach is the focus of an internal research project at the University of Cagliari which has as the objective of the recovery of the little villages in Sardinia and in particular the relationship between settlement and border areas. My study takes place in this project, with a deepening on the village of Cabras, a perfect research terrain for the development of the theme of project multi-scalar capacity. Cabras is placed in the most important wetland of Sardinia, characterized by the mouth of Tirso river, and the presence of ponds, drained marshland and the lagoon with the same name (Cabras Lagoon). In the midst of this wide regional water landscape it develops society that lives between agriculture and fisheries, and which derives its resources from two major funds, the lagoon, which until a few decades ago it was still a feud, and the field cultivated with cereals, rice, vines and olives. The territory of Cabras is divided into two parts, *Bennaxi* and *Gregori*, the first one is a fertile alluvial soil and with very good conditions for agriculture, the latter is better for settlement. The geological and hydrographic nature of the place has deeply determined the position of settlements in the whole area of the so-called Campidano Maggiore, so that Cabras is located at the end of a series of villages with the same distance from the river Tirso, in which the area of Bennaxi, the floodplain became both a support source, as the principal place of agricultural production, but also a means of defense against Tirso flooding. The villages are located on an ancient Roman road, the so-called *Via Maxima* leading from the Roman port of Tharros, passed Cabras and came to the Roman outpost of Forum Traiani, the seat of the Roman army in Sardinia.

The mutual relationship between habitat, road and water has always adjusted system and relations of urban and territorial scale. The theme of water then reveals additional complexity in the form as it is enriched with a system of irrigation canals radiating from Tirso as the main system and allows you to structure the surrounding countryside. The result is thus a supporting structure of landscape straight from the water system that has in the river Tirso its generator system and through the system of canals to reach individual plots that generate agricultural plot and through ducts leading intercept the main settlements. The regional scale talks about a very complex system, therefore, where it is sufficient to represent a superposition of the water system and infrastructure related with the distribution of villages in order to understand thickness of the landscape that can have the river and how the project needs to interact with the water factor.

The agricultural plot draws the countryside but also the urban form, as the center of Cabras shows deeply scored by a plant in which the vacuum dominates on full and in which the space between the houses, the heart of the block is actually a large crop of interior farmland that belongs to housing. It is a fabric in which farmlands are contained and in which the relationship between road house and garden is a step often direct and linear. The urban scale introduces us to

the theme of the relationship between settlement and settlement, road and agricultural plot. The growth of the city in the last hundred years shows its continuous attempt of the city to include parties of agrarian plot inside including it inside the shape of the city block and going to clash with the landscape water that crosses and order the agrarian plot.

The project is confronted with this, a system characterized by a wide water landscape, where Tirso hierarchizes a duct system that carry water to the countryside close in large tanks and piezometric towers at the margin with the city center. Water defines an invariant at the territorial scale, canals and water towers represent *iconemi* of urban. While the scale of the block controls the house that defines a filter between urban and rural interior of the block. The multi-scalar system lies in the strength of these invariants to define all scales, from wide scale river at the territory scale, to the water tower at the urban scale until the channels that arrive near the cluster, until the street and the towers that form the skyline of the city and define pathways and crossings, until the house which is the smallest unit, the atom of the settlement, that variously aggregated and compared with the elements that I mentioned above, draws the urban form.

The project can become an opportunity to mend the edge of the city through a system of *passing through public space* which is based on a structure of farmland, namely the canal that enters the city through a system of tanks, watering hole, and drinking troughs of the agricultural plot. The new urban tissue reinterprets the domestic blank isolates reasoning systems with different densities going to define a base tissue with high density but wide space dedicated to public space. The houses are all individual with a spread space dedicated to little vegetable garden, whose size varies in a coordinated and regulated manner. The public space is a very abstract space where the element dominates the wide square yard, the main trading place on the edge of the consolidated center and direct daily practice and calls for characters in this kind of space, in some cases very elongated, while in other an Italian square in a dense system. The project ends with a new definition of the edge, a line defined by the channel that closes the project and ideally it is linked to watering tanks that dot the agricultural plot. The relationship between architecture and multi scalar approach becomes a system of relations between the invariants of the land, the river and the water, the invariants of public space, the continuity of the wall, the landscape of *iconemi*, steeples and towers, and then the water at the scale of the city block with the channel and the trough that becomes the basis of a series of details that go beyond the architectural scale, through a coherence that starts from the analysis of the territory that in this sense becomes study and project in the same time (Figure 2).

Figure 2. Passing through public space.

The second project that I propose has been developed within the international competition European 12 which had the theme of Adaptable City, it was therefore required to teams to engage in interpretation of the theme in different contexts. Our choice fell on the center of Hognas, where it involved the construction of a new settlement and the issue of urban ecorhythms. The interpretation of ecorhythms and the territory of Hognas is one that has resulted in the definition of the project and on which it is inserted multi-scale survey. The city of Hognas is a historic

trading port in the south of Sweden, in the region of Skåne, overlooking Denmark and particularly important maritime crossroads between Helsingor and Copenhagen on the Danish coast and Landskrona, Helsingborg and Malmö on the Swedish coast.

This important port has sanctioned the birth of an industrial coal processing and manufacturing center specializing in quality ceramics. In addition to this all an agricultural hinterland with rape and potatoes fields, which mark the typical rural landscape of Skåne, dotted with farms and a growing mostly in large estates. With the closure of factories and the reduction of port traffic, Høganäs is faced with its current resources, the water and the sea, and the agricultural back end. The scale of the territory tells Skåne system with the network of relationships between Høganäs and infrastructural mesh that acts as a hub between the pole of Helsingborg and Halmstadt north and between Helsingborg and Stockholm on the other side. A landscape invariant is represented by the long field and the park series, often with a territorial importance, the green size becomes a key element in the urban scale which overlaps the mesh infrastructure, another element that defines a multi-scale is the railroad, settlement structure which divided historical coal production centers across Sweden and now abandoned.

The relationship between the green plot and infrastructural plot appears to be the dominant element in the landscape of Høganäs. These have become the axes of the generators of the new system of habitat that is proposed for this area. The choice is to define a unique infrastructure and green mesh percolating through the old railway and port system from large environmental park in the north to the south through green areas of the north-south axes and understanding the historic district of Gruvtorget. The wide green bands become public space and infrastructure, with bike paths and walking trails, overlaying a green and light plot to a heavy infrastructure that once ran through the area. On this system of relations with the existing, the project engages the theme of temporality and multi phase of the project, identifying crossings in green transversal axes generators of new urbanity which then joins in cluster systems with the possibility of increasing saturation in time (Figure 3).

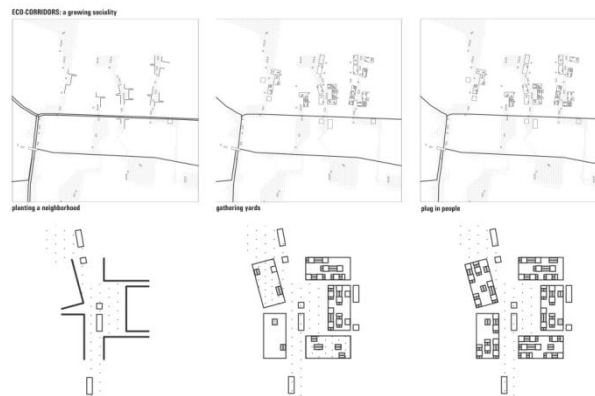

Figure 3. Høganäs, a growing habitat.

The cluster is positioned as a wood fence in public and defines the boundary between the percolating green and agricultural mesh that remains consolidated in the area. The idea is to define wide wood squares that interpret the theme of the public space of the urban centre and in this way try to find a dialogue with the tissue of traditional country houses that characterize Høganäs agrarian plot. Thus the cluster is generated as the sum and dialogue between historical elements, square wood and new elements. In this case the multi-scale project is divided on two fronts, the first is the multi-scalar system of the public space, from territorial arteries, to the space of the relationship among the houses, defined by the fence and inside the card. On the other hand we have the issue of multi-temporal and changeable and evolutionary possibilities of the project over time. The Adaptable city is becoming a place full of relations marked by a

green percolation through the countryside, the historic town and new agricultural plot and gives voice to territorial demands through the micro scale in different time scales(Figure 4).

Figure 4. Wood square with clusters.

Future perspectives

Thinking about the concept of multi-scalar allows us to tie analysis and design in a manner often inseparable and in this sense to tie it to the place deeply and exert the terms in which Carlo Socco speaks about landscape, defining it as the sense of a place as it is revealed to the perception (Socco, 2000). The force is entrusted to the relationship between objects and network, the multi-scale fact relies on a well-defined mesh, a rigid system to lean to the zoom-in and zoom-out using as a yardstick of comparison upon which to vary the certain mesh objects that are part of the signs and fit within a model of perception signs of the landscape which is based on elements that communicate at all scales and that provide the basis for the project at all scales of intervention. The project of Cabras and Hoganas show how deep analysis on the territory becomes the grid on which to perform the progressive zoom, the two elements of multi-scale flow rate, the water and the woods become defining elements of the spaces in 5 dimensions, in Cartesian space of three dimensions, the fourth dimension that refers to multi temporality and a fifth dimension that is the one related to the users and to sociability, since they become the new engine of social relations.

Reading the landscape is not to deny the precarious balance achieved and their continuous changeability or perfectibility, it means dealing with the inertia of the structures of the signs and the depth of the layers that make up the local listings. The multi-scale process has an obligation to balance between change and permanence, and it is the size of the length projecting multi-scale more than three dimensions. The research aims to identify a *transition between the scales* that creeps and lies within the rhizomatic structure of the landscape and identifies possible links and relation systems. The tension between natural and cultural value, between local and universal values, inevitably evokes the relationship between places and networks, long thought of as complementary metaphors, for the interpretation and design of the territories of the contemporary (Gambino, 1994). They may help to recognize the "territoriality of the landscape" in the wide meaning given by the European Convention. It is in landscape, as evidenced by the incessant interaction of the natural and anthropogenic dynamics, that the historical settlement takes its full meaning. In landscape the historic district dialogue not only with the "built cultivated fields" (Cattaneo, 1845), over the centuries by agricultural networks, water systems and systems of roads and infrastructure, but also with the presence of moving nature, often reluctant to any demarcation, pervades and diversifies the spaces surrounding constructed areas in various ways.

The relationship of man with the place, and through the places reside in living spaces. The relation between man and space is living, reflecting on its essence. (Martin Heidegger, 1975)

Conurbation in the Porto Alegre metropolitan region

Decio Rigatti

UniRitter – Laureate International Universities, Porto Alegre – Brazil. Rua Carazinho, 146 Ap.
04 90460-190 – Porto Alegre, RS, Brazil. E-mail: driga2000@yahoo.com.br

Abstract. *One of the main features of metropolitan regions is the spread of urban fabrics belonging to different municipalities and their tendency to conurbation, which can be uneven, presenting different growth speeds, morphologic peculiarities and different kinds of natural restraints. The parts tend to connect to each other, making up a spatial unit of a different scale and complexity where the whole and not only the parts of its structure follow a new logic. In morphological terms, when the conurbation is strong, its syntactic measures tend to be more robust than those presented by the parts. This can be measured through the Conurbation Index (CI), which compares the global integration of the parts with the global integration measures of the whole – the emergent structure. A theoretical model is presented, from which is analyzed the way the syntactic measures change as the urban fabrics interpenetrate each other. Empirically, nineteen pairs of contiguous municipalities of the Porto Alegre Metropolitan Region are examined, together with five wider systems made up of three or more contiguous municipalities in the same region. In addition, the same methodology used to produce the theoretical model was applied to two groups of municipalities, presenting different morphological features.*

Key Words: *Conurbation, metropolitan regions, urban growth, conurbation index, conurbation modelling.*

Introduction

Metropolitan regions can be understood as a product of the transformations held in the territory by a number of simultaneous phenomena. From the economic point of view, a metropolitan region means the agglomeration of activities over a territory more or less vast, which are distributed and enable to bring together relations of complementarity and interdependence like those that can be found in complex urban systems. This implies, in this sense that the logic of the economic background can be found within different patterns of production and reproduction of social relations. How specialized or diverse the economy is within a metropolitan region depends both on its role regarding a wider economical area, how connected or dependent it is regarding globalization processes, and on the relationships held inside the region itself.

From the social point of view, a metropolitan region represents an agglomeration of people and this is close related to the logic of the reproduction of the social/economic sub-systems. The distribution of the population, the patterns of their income, living standards, jobs, etc., depend on the way social structures relate to the economic system as a whole. Also in this case, diversity or specialization depends on the way the entire system works on space.

From the spatial point of view, metropolitan regions tend to represent a new scale of spatial organization and one of its main features is the tendency to conurbation, that is, the formation of spatial continuities which are produced independently of local spatial dynamics represented by the spatial units that made up the region as a whole.

The Porto Alegre Metropolitan Region

Briefly, in this case study it will be analyzed the main conurbation of the Porto Alegre Metropolitan Region – PAMR, in the State of Rio Grande do Sul, Brazil, made by 14 different municipalities, born in different times and for different purposes. Porto Alegre, Viamão and

Gravatái are the oldest cities and start their evolution from the second half of the 18th century on, in a time when Portuguese and Spanish crowns were fighting for a territory whose limits used to change according to several non-lasting treaties. These are the cases of cities that slowly evolve from small foundation cores. In the beginning of the 19th century the northern part of the region begins to be occupied by German immigrants and São Leopoldo is the first colony and the main centre for the occupation of this part of the State. Later on, Novo Hamburgo, Estancia Velha, Campo Bom, Portão and Sapiranga start their development as expansions of the São Leopoldo colonizing core. Porto Alegre was linked to the colonies (firstly with the German ones and, by the end of the 19th century, with the Italian ones, which occupied the remaining vacant land in the north-east part of the State of Rio Grande do Sul) through a railroad built in 1874. Along this railroad and within the PAMR new urban settlements were built around some of the rail-stations like Canoas, Esteio and Sapucaia do Sul. These are cases of urban areas that grew from rail-stations.

The entire region experiences a remarkable growth during and just after The Second World War, as a result of an industrialization process. The growth of the population that follows this process produces cities like Alvorada and Cachoeirinha which origins are based on consecutive land divisions promoted by urban developments for low-income dwellings and not in the evolution of a pre-existing urban core.

Following this socio-economic process, important national (BR) and regional (RS) roads were built, connecting the cities and the region to the national territory, like the BR-116, which runs from Brazil's South to North-east, crossing Canoas, Esteio, Sapucaia do Sul, São Leopoldo, Novo Hamburgo and Estancia Velha within the PAMR; the RS-030 and the RS-020 cross Cachoeirinha and Gravataí; the RS-118, connects the BR-116 to the BR-290 passing through the territories of Gravataí, Cachoeirinha, Esteio, Sapucaia do Sul and also of Alvorada and Viamão, though far away from their main urbanized areas (Figure 1).

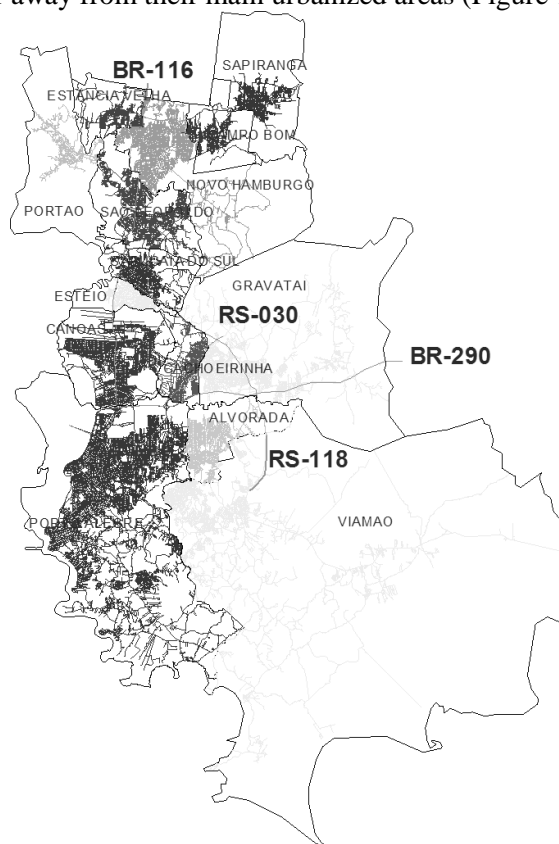

Figure 1. The Porto Alegre Metropolitan Region and the main roads.

From the 70's on, new national and regional roads that cross the region and the increase of regional and interregional connections took an important part in the configuration of the metropolitan space. Important roads built at that time are: the BR-290, connecting Porto Alegre to the coast until the north-east region of the country, running E/W from Porto Alegre Northern city limits and passing through the municipalities of Cachoeirinha and Gravataí; the RS-239, connecting Estancia Velha, Novo Hamburgo, Campo Bom and Sapiranga, close to the Northern limit of the study area; BR-386, connecting the metropolitan area to the North-Western part of the State.

One of the outcomes of this process is that the evolving urban areas begin to carry on roles that are not explained only by their internal logic, but can only be understood by the way they are inserted in an interdependent and expanding metropolitan system where the conurbation is one of its visible outcomes.

Spatial Conurbation and a theoretical model

A theoretical model was produced in order to simulate a growing conurbation process and to observe how this process affects the syntactic measures of the spatial outcomes.

The syntactic measures

In this paper it will be used four syntactic measures (Hillier, B. & Hanson, J., 1984) which help to describe the main morphological properties of the spatial systems to be analysed, as follows: a) Global integration (RN) – Integration is related to the notion of depth: in a spatial system, represented through the axial map, every line is connected to all others, directly or by using a number of intervening spaces. A shallow or integrated space requires a small number of intervening spaces to connect it to all others. On the other hand, deep or segregated spaces need more intervening spaces to connect them to all others. (Hillier, B., 1996); b) Mean depth – In a system, the mean depth informs about how shallow or deep the systems are, regarding the way every space is connected to all others. This measure directly affects the syntactic integration value; c) Synergy – Synergy is the statistical correlation between global and local integration. High correlations mean that a larger number of spaces are simultaneously globally and locally well integrated or segregated, representing systems where the global structure is better superimposed to the local structure; d) Intelligibility – Intelligibility is the statistical correlation between a global measure, (global integration) and a local measure (connectivity). It represents how it is possible to understand the global structure of a spatial system through locally given information.

The theoretical model

The starting point of the model is a regular grid with twice as much vertical than horizontal lines, with its correspondent syntactic measures (Figure 2).

In order to increase the complexity and to build up a conurbation, the same grid is placed contiguously to the previous one, slightly mismatched and with the line that divides one grid to the other belonging to both systems (Figure 3).

The main syntactic measures: mean global integration (RN), mean depth, intelligibility (correlation between global integration and connectivity) and synergy (correlation between global and local integration) are presented below the figures, showing how they change as one system is inserted in the other.

In this way, the resulting grid has the same number of vertical and horizontal lines. Mismatching the position of the grids allows us to observe what happens with the syntactic measures when one grid penetrates the other, step by step, that is, every vertical line of one sub-

system reaching one horizontal line at a time in the other subsystem (figure 4a, 4b, 4c and 4d), until one grid is completely inserted in the other.

This will produce a more compact and shallow system (fig. 5).

Figure 2. The basic regular grid.

Figure 3. The global integration of two original regular grids slightly mismatched and the syntactic measures of the grouping.

It is possible to observe that as the mean depth is reduced, the more compact is the resulting system in a constant pattern, the same happening with all other measures. These measures are good indicator of conurbation: compactness is responsible for the movement economy and the spatial integration is scattered all over the resulting system.

Another theoretical exercise made on the same grid which is important for the purposes of this paper was made testing the blocking of lines both in the limits between the two subsystems and in their periphery (figures 6a and 6b).

It is possible to compare this exercise with the analysis made by Hillier (1996) on the construction of the spatial integration: obstructions in the centre of the composition tend to reduce integration and push it to the periphery. On the contrary, obstructions in the periphery tend to reinforce the integration in the centre of the composition.

As Hillier says “A centrally located larger space integrates more than one that is peripherally located. (...) The more centrally a block is placed, the greater ‘depth gain’ or loss of integration” (1996:351-352).

For our purposes this is particularly important once we can analyze this process by looking at what happens in the limits of the municipalities we are interested in observing and where we can find some obstructions or interruptions within the urban fabric.

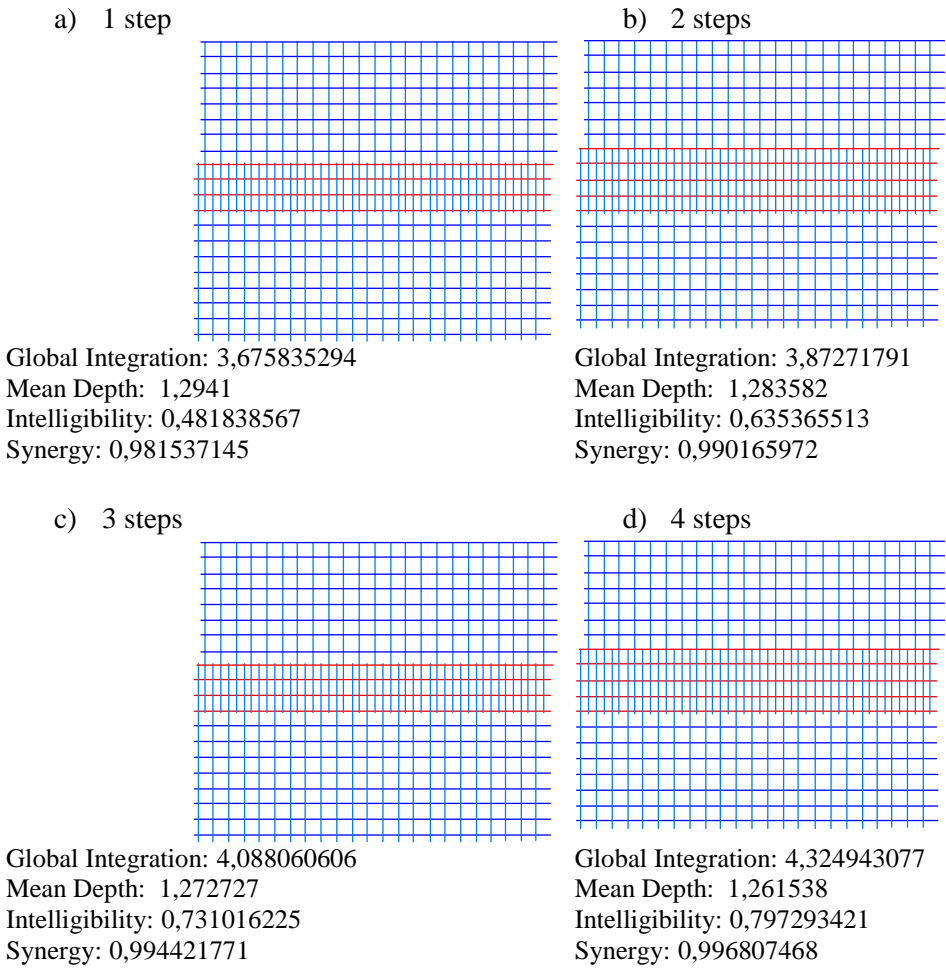

Figure 4 The global integration with the penetration of the grids, step by step (“a” to “d”) and the resulting syntactic measures.

Figure 5 The global integration of one original grid completely inserted in another one and the resulting syntactic measures.

Global Integration: 7.056082759
Mean Depth: 1.172414
Intelligibility: 0.797293421
Synergy: 1.0000000

Figure 6. The global integration of blocking of lines in the limits (“a” – top) and in the periphery (“b” – bottom) of the sub-systems and the resulting syntactic measures.

"a" - top:

Global Integration: 2.832373333

Mean Depth: 1.52

Inteligibility: 0.368356272

Synergy: 0.833686231

"b" - bottom:

Global Integration: 2.905639506

Mean Depth: 1.304348

Inteligibility: 0.45514709

Synergy: 0.950454979

The Conurbation Index - Ci

The previous theoretical model shows that the more one subsystem penetrates the other the mean global integration of this system is increasingly higher than the mean integration of the subsystems. Straightforward, we can propose the following conurbation index (CI): $CI = R / (\sum rn/n)$

Where CI is the conurbation index, R is the mean global integration of the grouped subsystems and $\sum rn/n$ is the mean global integration of the isolated subsystems divided by the number of subsystems. The higher than one is the index, the stronger is the conurbation.

It is proposed that in strong conurbations, syntactic measures tend to be more robust for the whole than for the parts. In this way, urban areas with strong conurbation are better explained in the way they work together than when they are considered separately.

In the theoretical model, considering a step by step calculation from the original grid – 0 step - until 4 steps of grid penetration in order to simplify the procedures, and also the results of the outcome of the complete penetration of the grids are presented in table 1, below.

Table 1 Conurbation Index - CI – in the Theoretical Model

	0 step	1 step	2 steps	3 steps	4 steps	complete
CI	0.6167293	0.6485320	0.6832683	0.7212614	0.7630549	1.2449132

What is possible to observe is that the Conurbation Index consistently grows as one sub-system become more and more inserted in the other. Also, the way the index grows in the step by step process is at a same rate from one step to the next one.

The Porto Alegre Metropolitan Region – Pamr - and the Selected Cases

Regarding the PAMR conurbation, considered as a spatial phenomenon, a deeper look into its spatial system reveals that there are different degrees of conurbation and interdependency among the constituent parts. Some spatial complexes - parts of the whole - seem to be better understood when seen together while others, in spite of belonging to the same conurbation, seem to keep their individuality regarding other neighbouring areas, both in terms of the space itself and their socio-economic features.

This paper will deal with the differences in terms of physical relations that can be found in the 14 municipalities considered here as the main PAMR's conurbation. A broader analysis was made, considering nineteen pairs of contiguous municipalities and five wider systems made up of three or more contiguous municipalities and the entire metropolitan area as well (fig.7).

In addition, the same methodology used to produce the theoretical model was applied to two groups of municipalities.

The study cases were analyzed through different syntactic measures, but the Conurbation Index suggested in this paper takes into account basically the global integration measure, once it captures key aspects of the urban layout.

This index may represent both a limit to the conurbation process, cases when CI is high or, on the other side, it may either represent potential possibilities of conurbation or restrictions to its process according to the possibilities of the urban fabrics to be more or less easily connected.

The case studies presented here were selected based on common sense, like: 'we cannot identify where municipality X ends and municipality Y starts', both in terms of the observation of geographical data and also in the way locals describe their city limits.

In this group of municipalities the notion of compactness seems to be a very important feature of neighbouring urban areas.

Figure 7. The PAMR and all Contiguous Municipalities Examined in the Selected Cases.

In the table below, is presented the results for all possible pairs of contiguous municipalities and also for the grouping of more than two contiguous municipalities.

Table 2. Conurbation Indexes for Contiguous Municipalities in the PAMR and for the Region.

Municipalities	Conurbation Index - CI
Alvorada + Viamão	0.727329065
Cachoeirinha + Canoas	0.730430083
Cachoeirinha + Esteio	0.506144471
Cachoeirinha + Porto Alegre	0.690948392
Campo Bom + Novo Hamburgo	0.767137911
Campo Bom + Sapiranga	0.771477628

In red, is marked the case where the CI is higher than one; in yellow, the group of cases with the higher CI's (close to one) and in blue, the group of cases with the smaller CI's. The group of cases with intermediary values of CI remains colourless.

For the purposes of our analysis we will examine only the cases presenting high and low conurbation index once they are more useful for the analysis in the sense that they represent border cases.

The conurbation between Esteio and Sapucaia do Sul is the only one with a CI higher than one, what is interesting for our study, because is an example of two cities with blurred limits, with juxtaposed city centres, sharing the syntactic integration core when examined together.

Some regularities were found among the municipalities presenting higher and smaller conurbation indexes. The main features of the grouping of cities with high CI are (fig.8): (i) They are connected by well integrated lines, which penetrates the sub-systems; (ii) We find two different kinds of distribution of spatial integration: a) one of the sub-systems concentrates most of the integration core, like in the case of Porto Alegre and Viamão; b) the other five cases presenting high CI present the same features, with a strong concentration of integration in important roads (BR's and RS's) that cross and connect the spatial systems. They are connected through their urban fabrics and not only by isolated lines.

As for the grouping of cities presenting low conurbation indexes, the main regularities found are (figure 9): They are connected by a well integrated line, which links both sub-systems but does not penetrate each other; The sub-systems are connected by a small number of lines – mostly by only one; There are no urban fabrics on the city limits but only isolated lines.

In the case of Novo Hamburgo and Gravataí, which have the smaller conurbation index within the cases, the sub-systems present independent integration cores. The distribution of the spatial integration of the joined cities reproduces the distribution of the spatial integration of each of the considered municipalities. In the other three cases, the spatial integration is strongly concentrated in one of the sub-systems. These results can be biased by the way the continuous urban fabric of the metropolitan region is separated for this analysis. For example, in the case of Novo Hamburgo and Sapucaia do Sul (the second smaller CI), when their fabrics are joined with São Leopoldo, whose urban fabric lies between Novo Hamburgo and Sapucaia do Sul, one of the highest CI is produced, as we can see in the table above.

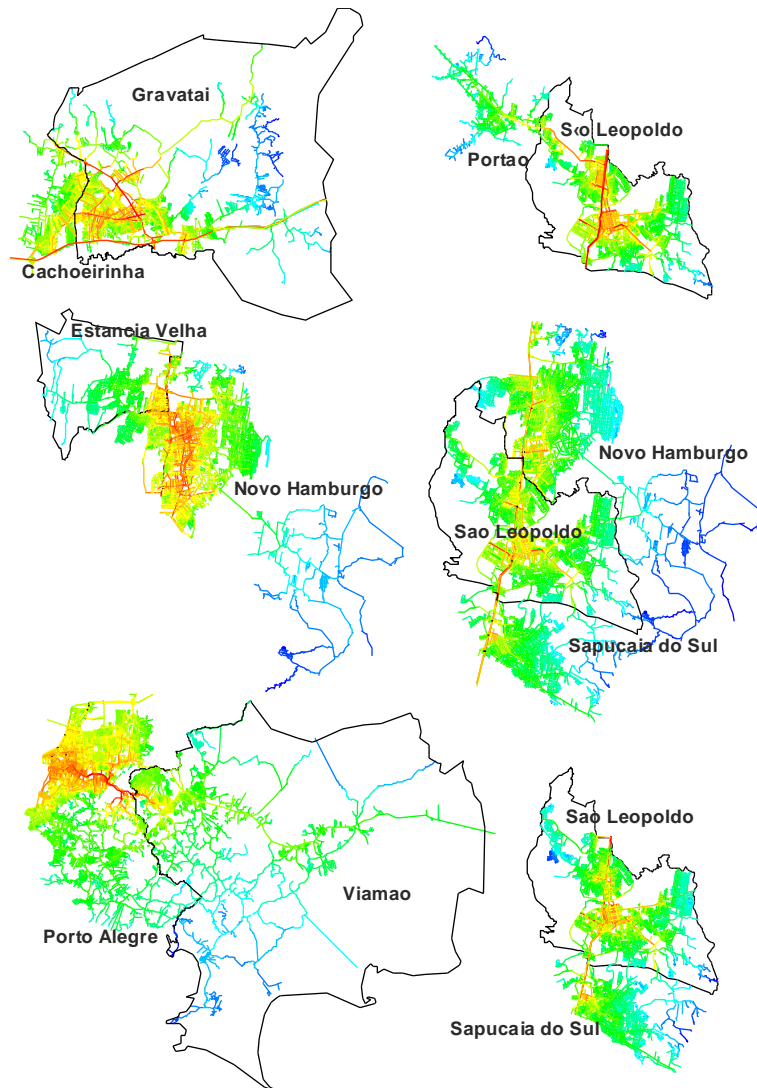

Figure 8. Cases with the Highest Conurbation Index. In black, the limits of one of the municipalities.

In order to observe what happens in actual contiguous spatial sub-systems in terms of their conurbation indexes, when the procedures proposed for the theoretical model are applied (3.2, above), two different sub-systems were analysed: Sapucaia do Sul together with Esteio - the conurbation with the higher CI and with a dense urban fabric in the city limits-; and Gravataí and Cachoeirinha, presenting a high CI but with some vacant areas along the city limits.

The first step was to extend all lines close the limits of each sub-system and one step apart of it until they could reach the lines which belong to the city limits. The second step was, from the

previous stage, extending all lines until the first line inside the sub-systems was touched, and so on.

This exercise was limited to three extensions of lines, although it could be done until every line of every sub-system crossed each other as it was made in the theoretical model. In this way, the lines were extended but no new lines were created, keeping the same the size of the systems in terms of the number of axial lines from the beginning and with the step by step extension of lines. The results for the syntactic measures and for the conurbation index are presented in Table 03 for the grouping of Sapucaia do Sul and Esteio and, in Table 04, for the grouping of Gravataí and Cachoeirinha.

Step 0, in both cases, means the original situation of each sub-system before the extension of lines.

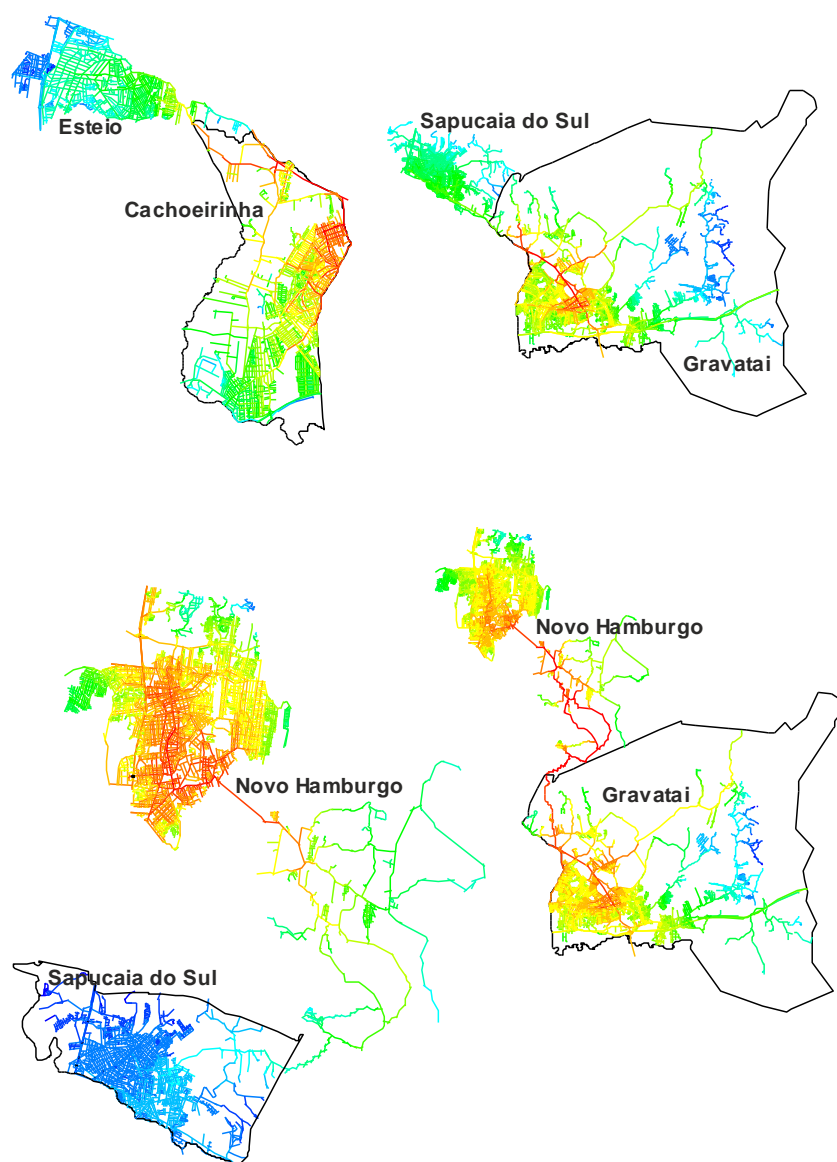

Figure 9. Cases with the Lowest Conurbation Index. In black, the limits of one of the municipalities.

Table 3. Syntactic Measures and Conurbation Indexes for Sapucaia do Sul + Esteio, with Extension of Lines

Extension of lines	SAPUCAIA DO SUL AND ESTEIO				
	Mean Depth	RN	Intelligibility	Synergy	IC
0 steps	5.8708294	1.04971959	0.412122091	0.729756479	1.05085936
1 step	5.844212	1.054441401	0.418072177	0.735514995	1.05558629
2 steps	5.710889	1.07978369	0.442237296	0.753198329	1.08095610
3 steps	5.686107	1.081900806	0.455537553	0.761252168	1.08307551

Table 4. Syntactic Measures and Conurbation Indexes for Gravataí + Cachoeirinha, with Extension of Lines

Extension of lines	GRAVATAÍ AND CACHOEIRINHA				
	Mean Depth	RN	Intelligibility	Synergy	IC
0 steps	10.1811	0.692776914	0.300814959	0.581291802	0.84343863
1 step	10.16005	0.696239306	0.303002426	0.588722765	0.84578566
2 steps	10.13262	0.695886595	0.309784275	0.593726679	0.847225
3 steps	10.09147	0.701809028	0.323290262	0.603776164	0.854435

In both cases, the extension of lines, because they produce a thicker urban fabric in the centre of the systems (Hillier, 1996:352), improves all syntactic measures, while Mean Depth is consistently reduced. Another important observation is the thick urban fabric created by the extension of lines when they penetrate each of the considered sub-systems.

Particularly in the case of the conurbation between Gravataí and Cachoeirinha, it is possible to say that the conurbation can be stronger or weaker depending on the way the existing vacant land in the limits of the municipalities will be occupied along time, creating a new pattern of spatial integration. In this case, the extension of lines in the limits of the municipalities eventually produces the reduction of the vacant land and their substitution by a denser urban fabric, as the number of steps grows.

Final Remarks: What Produces Conurbation?

At this point, from the theoretical modelling and from the actual cases presented in this paper, it is possible to make some preliminary observations about the conurbation process in the Porto Alegre Metropolitan Region. At a more theoretical level, it is possible to understand when we can talk about conurbation as a general process, concerning the relationships among different spatial systems. Furthermore, conurbation is, most of the times, a process resulting from many of the considered scope of variables working together and not only from one or another of them, as described below.

Spatial contiguity

Both in the theoretical examples and in the case studies, it was shown that, although the contiguity of the urban fabrics is an essential aspect of conurbation, it does not suffice to improve conurbation. The spatial contiguity may in some cases to cover-up sub-systems that are divided by a joining line, which may separate discontinuous urban fabrics like in the original situation of the theoretical model showed in figure 3 above.

Compactness

The compactness of the analyzed urban layouts seems to be a necessary condition for the conurbation, but is not always sufficient. Some of the studied cases present a compact urban fabric in the grouped cities, but not a good result in terms of conurbation index, when examined the spatial structure of the joined municipalities and their syntactic measures as seen above. In both cases, the axial lines that lie along the city limits actually unite two different and unconnected urban fabrics that seldom present lines that cross the city limits and penetrate the neighbouring municipalities. What the studied cases show is that compactness is an important feature of conurbation when joined urban areas share spaces that not only touch each urban fabric but, most importantly, interpenetrate each other. Thick urban fabrics in the limits of the sub-systems presenting a significant number of axial lines that are part of both sub-systems, more consistently produce higher conurbation indexes. In these cases, the conurbation tends to be not only a peripheral phenomenon – in the sense that it only touches the sub-systems – but produces another kind of spatial system. In this way, the logic of the grouping of cities prevails over the logic of the parts.

Depth of the spatial system

When the grouping of two different urban layouts is able to reduce the Mean Depth of the resulted spatial system, there is an improvement of the conurbation index once it directly interferes in the results of the Global Integration (R_n) values and the other considered Syntactic Measures of the conurbation.

The Distribution of the Integration

The case study of Esteio and Sapucaia do Sul joint together, which presents the only Conurbation Index bigger than 1, allows us to observe other features that seem to contribute to rise the Conurbation Index, namely, the spatial distribution of the Global Integration (R_n) or, more specifically, the Integration Core of a group of cities. In this case, the Integration Core of the grouped cities tends to produce a centrality that both covers and contains the centralities of the parts. Even if the new centrality does not eliminate the centralities of the parts or the identities of every municipality, we can find proximity and continuity of the city centres within the centrality of the joined cities as an important aspect of the conurbation. On the other hand, in the case of the lowest conurbation index, between the municipalities of Novo Hamburgo and Gravataí, the distribution of the integration core of the joined sub-systems keeps almost intact the integration cores of the parts, almost if the grouping of the spatial sub-systems does not affect the results of the whole. The syntactic independence of the parts affects the results of the grouping sub-systems, producing low conurbation index. We can expect, as in this case, that socio-economic relationships and interdependence tend to be reduced between these two municipalities and, also, that interdependence tend to be established with other municipalities where urban morphology is able to facilitate mutual rapports.

Axial lines or urban fabric?

According to the results of the actual cases examined in this paper, it is possible to say that, if single axial connection is important to produce conurbation, more important is the connection through urban fabrics. The thicker they are in the city limits, the higher the Conurbation Index is.

Is conurbation a spatial quality?

It seems evident that a high Conurbation Index does not implies in qualitative aspects in the functioning of Metropolitan Regions. In fact, strong physical discontinuities that can be found among cities like rivers, vacant land, large natural parks, flooding areas, for instance, can produce low Conurbation Indexes. Nevertheless, low or high conurbation index does not mean that one is better than the other, but it only shows the diversity of spatial roles that can be found in metropolitan regions and some limits to produce spatial conurbation within the region.

Urban growth and the two paradoxes

Emergent processes are able to produce higher conurbation indexes among contiguous urban fabrics through the overcome of the centrality and visibility paradoxes (Hillier, 1996), but only when spatial transformation is required for the functioning of the metropolitan structure as a whole, following both the local goals and the global objectives as well.

The research findings explained in this paper allow us to identify common or different patterns of conurbation, with similar or different outcomes among different groups of contiguous urban areas. It is possible to suggest a conurbation index that is able to explain about the way parts and wholes produce configurational features that can be measured and compared. This Conurbation Index can easily identify the impacts of actual or future urban expansions of neighbouring urban areas, allowing us to understand how this process can lead to public policies that, instead of competing with each other, could promote joint efforts in order to solve urban problems that tend to be shared between the municipalities, specially taking into account that, in Brazil, there is no urban planning at the regional scale, but only at the local scale.

Configuration of urban grid and the relationship between apartment buildings location: case study in Florianopolis, Brazil.

Amanda Corrêa

Universidade Federal de Santa Catarina.

E-mail: amanda@carvalhoepatrimonio.com

Abstract. *The verticalization process is one of the most determining factors of the production and growth of the cities, since it allows the “multiplication” of urban land and its profit maximization. The location is an important factor in this process and, among other things, is related to the configuration of the urban grid, which conforms to a great extent the pedestrian movement on the grid (Hillier et al, 1993) and is able to make certain spaces more or less attractive, thus assigning greater or lesser degree of probability for these areas to be developed or not. The aim of this paper is to investigate the patterns of configuration of the urban grids associated with the location of apartment buildings in the central area in Florianopolis. In order to do this, we used the Space Syntax Theory (Hillier and Hanson, 1984; Hillier et al, 1987). Its two main measures, integration and choice, were applied in global (Rn) and local (R3) scales. Results showed that apartment buildings are mostly located on both globally (Rn) and locally (R3) highly integrated spaces. On the other hand, for the choice measure buildings are situated in medium global choice (Rn), and medium to high local choice (R3). Thus, apartment buildings seem to prefer locations close to the rest of the city, but which, however, prioritize relatively quiet roads detached from the passageways to other spaces outside the center.*

Key Words: *Verticalization process, space syntax, configurational characteristics, high-rise buildings.*

Introduction

In the growth and urban densification process, the profit motivated by the real estate is one of the most decisive driving forces (Krafta, 1994; Krafta, 1999). In this process, the verticalization is a key way by which profit is maximized through the intensification of capital applied in the same location and the highest rate between built-up area and land area that equates to a greater "productivity" of the real estate activity. In this dynamic, the role of location is essential.

The attractivity of certain locations is related to the quantity and quality of existing infrastructure; the accessibility to the city center, to other secondary centers of retail, trades, services and jobs; the natural attributes such as beaches and interesting views; and indication of status and socioeconomic levels associated with certain areas of the city (Gonzales, 1985; Somehk, 1997; Abramo, 2001; Villaga, 2001). Since the price of the construction does not change significantly in different areas (Gonzales, 1985; Krafta, 1999), property prices are the determining factor for maximum profits on urban land.

However, the "best locations" from the point of view of the developers are not necessarily the same from the point of view of those who will use the building. The best locations for the developers, are those that allow them to extract greater profit, which does not mean that they are more accessible to downtown or have greater quantity and quality of infrastructure. Krafta (1994, p. 77) states “*Land is bought in relatively poor locations, as an individual commodity, and sold as part of new buildings, as new, good locations.*” There is therefore a delicate balance between a cheaper land, which reduces the cost of housing production, and a location with enough quality to attract dwellers. Understanding this balance can, therefore, help to better understand the dynamics of urban production and reproduction and the role that location plays on it.

However, the location is traditionally described considering, at the local level, the qualities immediately adjacent to the land (infrastructure, neighborhood socioeconomic status, etc.), and its environment qualities. Globally, it generally operates in terms of the metric distance to the CBD – *Central Business District* (Capozza, 1989). However, since at least the 80's, more refined ways to characterize and differentiate intra-urban locations were developed, such as those introduced by configurational analysis, some of which brought by the theory of Space Syntax (Hillier and Hanson, 1984).

The aim of this paper is to investigate the patterns of configuration of the urban grids associated with the location of apartment buildings in the central area in Florianopolis. We used two different syntactic measures, as we shall see, which capture different properties of the location in order to answer the following questions: considering all streets in which apartment buildings could be located, in which these streets did they actually appear? And what are the characteristics of the chosen streets regarding proximity and centrality to other streets of the urban system and its more immediate surroundings?

In order to answer these questions, we mapped the location of 697 apartment buildings in the center of Florianopolis and compared the configurational characteristics of these locations with the characteristics of the system as a whole, to try to identify significant differences.

Literature review

Dynamics of urban growth

Much of the dynamics of urban growth is driven by the pursuit of profit. This, in turn, is directly derived from the difference between the final selling price and the cost of housing production, including not only construction costs, such as labor and materials, but also taxes, duties and projects, and especially the land. According to Krafta (1998) and Gonzales (1985), the cost of construction tends not to vary greatly with the location within a particular urban area, provided that the buildings being compared have materials of similar quality as well as similar levels of technical and constructive complexity. Thus, the larger price variations properties are due to the price paid for the land.

This, in turn, is strongly influenced by its accessibility to other parts of the city (Capozza, 1989; Villaça, 2001). Therefore, more accessible areas tend to be more expensive, because they: a) minimize the costs of travel; and b) possess greater amount of social labor invested in its environment in the form of public infrastructure.

According to Krafta (1994; Krafta, 1998) areas with potential are "discovered" by developers, who build it and sell its real estate products profitably. By being the first, earn higher profits, since the price paid initially by the land is still low, in a process analogous to that of technological innovation in companies (Harvey, 1985 apud Krafta, 1994), to the point where the initial location advantages become disadvantages, as the value of the land increases. Other developers follow the same way in search of equally large profits, but with one difference: when they arrive, the price of land is no longer the same.

The cycle repeats with dwindling profits and one possibility is that, for the investment to be worthwhile, even at the cost of higher land, there needs to be a greater concentration of capital in that location. This is achieved by increasing the level of construction, changing it from, for example, a residence for middle class to upper class, or by increasing the relationship between the built-up area and the land area, that is, the verticalization (DiPasquale and Wheaton, 1992; Krafta, 1998).

Locational characteristics

Several goods that meet human needs are treated as commodities at one time or another. The same happens with housing, which is directly related to the real estate. Housing as a commodity

depends on a very important factor for their appreciation, its location. As noted above, the housing production, seen as a mechanism for generating profit, largely depends on the prices obtained when buying the land and when selling it as part of a new development, whereas these prices are closely related to the choices of location.

Villaça (2001) states that the quality of the location is the main component of land value “Urban land is only of interest as 'land-location'”, that is, as a means of access to the entire urban system of the entire city (Villaça, 2001, p. 74). Gonzales (1985) also states that the locational characteristics are dominant in the valuation of urban properties.

For residential uses, what are the factors that constitute a good location? The first factor is the presence of urban infrastructure (Gonzales, 1985; Somekh, 1997), represented by the existence of favorable conditions for urbanization and essential services. Another key factor is its accessibility to other parts of the city (Villaça, 2001), especially as perceived proximity to the main center and secondary centers of trade and services (universities, shopping centers, etc.) and others (Lynch, 1984; Batty, 2009).

Besides these factors, the scarcity of urban land, according to Gonzales (1985), combined with the qualities acquired through the status of the different sectors of the city, transform the urban land on a rare commodity. Thus, these areas are capable of producing enterprises with superior value to their production prices, especially in cities with significant growth. Under these conditions, the author states that it is possible to obtain the so called monopoly rent (MR), a determining factor in the extent of urban land prices. The MR varies according to the quality level of the project and location (as is the case, for example, in coastal areas), related to their condition and rarity, and the ability to pay of consumers. This quality is attributed to the lot status created “spontaneously” from the growth of the city or zoning, which allocates and uses special qualifications to residential areas.

The Verticalization in Brazil

The fast and intense process of growth in medium and large cities, both spatially, as population, has attracted the interests of a dominant economic class, especially developers. Thus, among the various forms of capital reproduction on urban land, the process of vertical integration has been a genuine innovation in the capitalist city. Thus it is clear that the building height is part of a strategy of capitalist interests, which ends up changing the urban landscape and the way of living of citizens (Tows and Mendes, 2011; Ferreira, 2012).

Conceptually vertical integration involves the notion of high-rise building or skyscraper. Somekh (1997) defines as the multiplication of urban land, made possible by the use of the elevator and points out that the construction of the first skyscraper in the city of São Paulo in the 1920s initiated an intense process of urban change that extends until today.

At the beginning of the twentieth century the production of vertical integration in Brazil began to expand due to factors such as the use of electricity, the use of elevators (Somekh, 1997), in addition to technological innovations in the area of construction applied to structural systems (Töws and Mendes, 2011).

Although the production of urban space is related to capital, political and cultural factors should also be considered, as the ideological spread of progress, development and modernity, associated with the symbolic dimension of this vertical integration in the urban context (Ferreira, 2012; Ramires, 1997).

From the readings made on the process of verticalization in Brazil some aspects can be listed briefly. (1) The verticalization is a feature of Brazilian urbanization (Mendes, 1992; Souza, 1994; Ferreira, 2012); (2) The verticalization is related to the modernity idea (Ferreira, 2012; Ramires, 1997; Ramires, 2011); (3) Fast increase (Ferreira, 2012); (4) It is characterized by a predominance of residential buildings as opposed to services, contrary to what occurs in other countries of the world (Ferreira, 2012; Souza, 1994); (5) The process of verticalization was made possible by a revolution in the way of building, both with respect both to new techniques and the use of different materials (Somekh, 1997; Ramires, 2011; Töws and Mendes, 2011); (6)

The vertical construction is also responsible for significant impacts on the urban structure, particularly social, and the value and use of urban land (Ramires, 2011); (7) The State assumes the role of urban space producer through the regulation of its growth (Ramires, 2011; Somekh, 1997); (8) The market logic is intrinsic to this process (Ramires, 2011; Somekh, 1997; Villaça 1986; DiPasquale and Wheaton, 1992).

As seen above, the location is able to exert a great influence in land values. Thus, Villaça (1986) points out that the location can be characterized as one of the engines that drives the process of verticalization and acts as a major contributor to urban sprawl.

Space Syntax and intra-urban location

The Theory of Space Syntax (TSS), developed by Bill Hillier, has as one of its main features the emphasis on the importance of the urban layout configuration. It was derived from the observation of the city and the attempts at trying to understand the relationship between physical aspects and social interactions. For Hillier (2009), TSS has always sought, first of all, a descriptive theory of the spatial form of buildings and cities.

To understand the theory of Space Syntax it is important to understand its basic principle, which is the natural movement. According to Hillier et al (1993), a significant portion of all pedestrian movement is determined by the road system configuration, that is, the way the roads and other public spaces are related to each other. This portion of the movement, that depends only on the configuration and, therefore, does not consider the location of the attractors (trade, services, housing, urban infrastructure, etc), is called Natural Movement (NM).

The theory of Space Syntax has two main measures: Integration and Choice. The first is a measure of closeness, while the second is a measure of centrality or betweenness. For both measures, the spatial unit adopted is the axial line, defined as the greatest straight lines capable of covering the entire system of open spaces (Hillier and Hanson, 1984).

Integration measures how close an axial line is from all other lines in the system. This proximity is calculated from the average number of changes of direction required by one line to reach all other lines. Therefore, the measure of integration is based on the depth of each axial line, representing the average topological distance from one line to all others in the system. Thus, Hillier et al. (1993) states that, the greater the number of intermediate spaces between any two points, the greater its depth, and therefore, the lower its integration.

The measurement of the average depth may be calculated according to a determined fixed radius, also topological, called the local Integration. In this case, the integration of an axial line measures how close (configurationally) this line is in relation to its immediate surroundings. This location is normally radius equal to 3 (R3) but it can also be 5, 7, 9, or any other desired number.

Several empirical studies (Hillier and Hanson, 1984; Hillier et al, 1993; Penn et al, 1998; Hillier and Iida, 2005) found evidence that integration is strongly associated with other urban patterns, such as land use and value and especially pedestrian movement patterns. According Hillier et al. (1993) the configuration of the urban grid is what guides new construction and new uses, since according to the authors some areas may have greater or lesser degree of potential of being built or rebuilt, as they are in areas more or less integrated into the system.

The second measure used in the study is Choice, which can also be applied on a global or local level. According to Hillier et al. (1987), the choice measure indicates the probability that a certain space is part of the minimum path between all pairs of system space.

Therefore, while the Integration measures the closeness between a space and all the others, the choice measures its centrality in relation to other pairs of system space. This means that they capture different properties of spaces and therefore may help clarify the different roles that the same space can play. Integration, therefore, captures the movement 'from-to', since it is a measure of closeness between origins and destinations. It assumes that, on average, origins and destinations closer to each other tend to generate greater momentum than origins and destinations that are far apart from each other.

On the other hand, the Choice captures movement through the space, that is, that movement which is not necessarily generated at the same place but passes by it, having been motivated by the interaction between the other two spaces. Although this difference is subtle, it is clear: we can think of spaces that are in shortest paths of other spaces without, however, being very close to all other areas of the system.

Applied to this study, 'Integration' and 'Choice', can help to clarify the preferences location of the apartment buildings with regard to these two aspects.

Methodological procedures

Produced by Grupo Desenho Urbano e Paisagem (GDUP), the axial map of the urban agglomeration of Florianópolis was used which has 22,369 lines, and then extracted the syntactic measures Integration and Choice (Rn and R3) of the central area of the city of Florianópolis.

Were raised by the Municipality of Florianópolis real estate cadastre data, updated in 2012 and, thereafter, selected lots that have apartment buildings with 3 floors. In the central area, these account for 476 apartment buildings lots, while the city has a total of 2064 units, according to the registration database. From these data, all axial lines that have apartment buildings were identified.

Then, the spaces (axial lines) that had apartment buildings were compared with the total axial system of the Center of Florianópolis, to identify how (and if) the first differed from all the lines of the Center. The first comparison was made visually, trying to identify patterns that were best captured by this way, and that would probably be more difficult to capture through descriptive statistics (mean, mode, median, etc.).

These statistical measures were part of a second comparison, to verify more quantitatively, the differences between the verticalized spaces and the system as a whole to assess whether, overall, the apartment buildings were located in areas more or less integrated than the average system, both globally and locally. The same check was made to the measure of choice.

Case Study: Florianópolis

Capital of the State of Santa Catarina, Florianópolis is located between the geographical coordinates 27 ° 23 'and 27 ° 50' south latitude and 48 ° 21 'to 48 ° 21' west longitude from Greenwich, with an area of 443.36 km² which is divided between its continental portion and insular and has 421 240 inhabitants (IBGE, 2010).

Florianópolis is now a tourist hub of the country and recently was named the third best city in Brazil to live, according to human development index published by the UNDP (PNUD, 2014).

The process of urban sprawl in Florianópolis

In the early twentieth century Campos (2009) states that Florianópolis was a provincial town, its structure was seen as summarizing land to what is now the city center and mainland portion. However it was in the early decades of this century that a number of modifications started through construction, responsible for new investments.

From the 1950s, is significant urban expansion of the city, which happens to have one, however chaotic accelerated growth. In this period the city hall ordering the first master plan for the city, since so far there has been little state interference regarding actions planned in the urban area of the city.

For Campos (2009), the installation of various government agencies in 1960, mainly the federal university of Santa Catarina, attracted a significant growth and development for the city, hence urban sprawl of the city and begins the vertical expansion in the city center.

The construction of the BR101, in the 1970s, became the fastest shifts, encouraging, according to Coelho (2012), the process of implementation of state highways, especially the SC401, linking the center to the Casnasvieiras beaches, boosting the city. According to Campos (2009) diverse investments in urban infrastructure were made during this period in order to develop the city. The construction of new bridges, Colombo Sales Machado and Pedro Ivo Campos, along the north and south embankments, enabled the urban expansion, as well as bridges, roads and double track constructed around the island. As well as across the country, in the 1970s, Florianopolis experiences its first real estate boom, this is when there were the first large residential developments, deployed in the city center, Beira-Mar Norte avenue neighborhood and close to Trindade.

With the process of economic recession that hit Brazil in the 1980s, Campos (2009) states that some major construction of the city give way to construction of smaller, thus the building which concentrated in the city center and had in average 12 pavements, this new environment, migrate to the suburbs and spend to produce buildings with 4 pavements, initiating the horizontal expansion of the city.

After the crisis of the 1980s, the revival of industry occurred in the 1990s, when many buildings over 12 pavements began to be built in Florianopolis.

From the 2000s occurs in the metropolitan region of Florianopolis a great "real estate boom", the city becomes a dream of consumption for various national as well as international social classes, mainly attracting people from the states of Rio Grande do Sul, Paraná and São Paulo, as well as neighboring countries in search of quality of life. This scenario turned out to further boost the construction industry, contributing to a major urban expansion that began a widespread vertical city.

Global Measures

To identify the configurational characteristics of the streets which happened the process of apartment building in the central area of the city of Florianopolis, these were analyzed on a global and local scale, using the space syntax measures described above: Integration and Choice. The apartment buildings are located in 154 axial lines within a local environment of 642 lines in the central area. Figure 1 Shows the map of Integration and Choice radius R_n and finds apartment buildings.

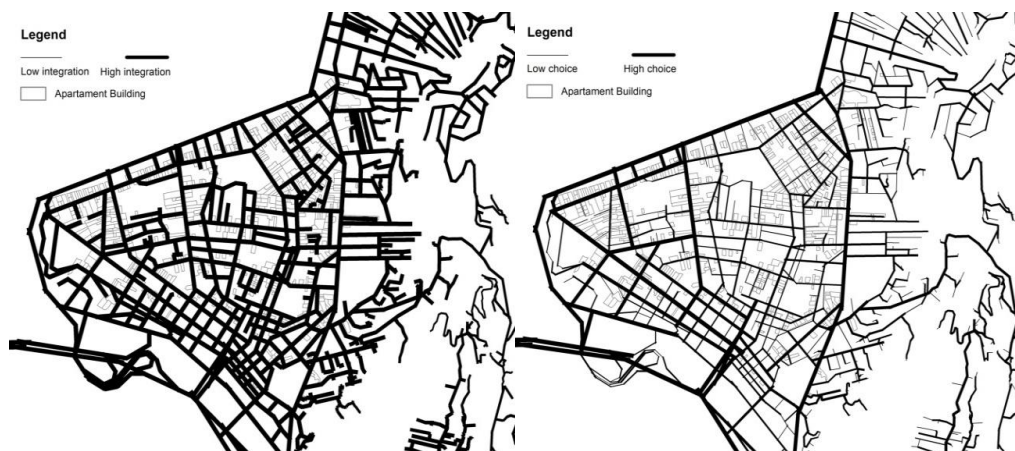

Figure 1. a. Integration R_n of the central area | b. Choice R_n of the central area.
Source: Grupo Desenho Urbano e Paisagem (GDUP) UFSC. Compiled by: Authors.

Looking at the study area in relation to the extent of integration Rn, one realizes that the entire cut has high level of integration with the global system, that is, all the buildings are coming from other areas of the city (a consequence of the fact that the cut represent the central area of the city). Yet, clearly the predominance of apartment buildings on high weight lines in Figure 1a. We can also notice a tendency of these buildings become more concentrated in the center and north of the cut, with low occurrence in the southern portion. This happens probably for historical reasons rather than by configurational reasons, since the southern area corresponds to the Historical Center of the City, where there are lots of historical buildings preserved with low number of floors.

As for the measure of Choice Rn, we see in Figure 1b that few streets of the central, are part of the shortest paths to other areas of the system, that is, there is a small amount of lines that carry these connections, while others remain secondary. In terms of density, this occupation, however, noticed that the streets with greater choice have higher concentration of apartment buildings, while, as the streets are internalized and become less "passing", the concentration decreases.

This relationship between the measure of integration Rn and Choice Rn, can be enhanced in Graphic 01 below. The black dots represent the streets where there are apartment buildings, while the gray dots represent the total streets of the central area.

Figure 2. Integration Rn X Choice Rn. Compiled by: Authors.

In this Figure 2 it is possible to identify streets where there are apartment buildings that have high global integration, being located in the far right portion of the set of points, but low choice global.

Local Measures

When analyzed on a local scale, the streets behave differently. Observing figure 3 below, the apartment buildings are located on streets from medium to high integration, while for the measurement of Choice, the location of apartment buildings is mostly on streets with a high level.

Figure 4 below shows the relationship between Integration and Choice R3. In this graph, we can identify that the deployment of apartment buildings focuses on the process of medium to high local integration and a few streets stand out for the high rate of choice R3.

Numerical Comparisons

Mean syntactic measures for the center as a whole, and for the streets with apartment buildings, are given in table 1. Comparing the values of two columns, we see that measurements of streets, where there are apartment buildings, is sensibly larger, with emphasis on measures of local radius (R3), especially the choice, in which the streets of the central area where there are apartment buildings is 131.41, against 51.47, the general average of the center (up 255.3%) .

Compared with measurements of choice, variations of Integration compared between all the streets downtown and only those with apartment buildings, listed in the third column can be considered small (107.7% and 133.6%). This may be an indication that the key to understanding the criteria of location, from the point of configurational view, is in the choice and not on Integration, at least for the selected area for this case study, characterized by a central area in which virtually all integration values are high, that is, there is relatively little variation.

This impression is reinforced by the histograms of space syntax measures in its two scales of analysis shown below.

Table 1. Means of syntactic measures of central area streets. Preparation: Authors.

	<i>Centre – All streets (624)</i>	<i>Centre – streets with apartment buildings (154)</i>	<i>Diference (%)</i>	<i>Centre - streets with apartment buildings (154) Weighted Average</i>
Integration Rn	0,26	0,28	107,7%	0,28
Choice Rn	3.447.193,31	5.364. 760,75	155,63%	28.020.368,28
Integration R3	1,10	1,47	133,6%	1,58
Choice R3	51,47	131,41	255,3%	356,43

Figure 5. Histograms of syntactic measures of the streets of the central area. In light gray, the histogram of the streets where there are apartment buildings.

Through the histogram is also possible to identify most of the streets of central area have a high rate of integration Rn, and moderate to high level of integration R3. For the measurement of choice, on the global scale, the vast majority is close to 0, however the few streets that have

significant value collaborate to high average which is 3,447,193.31, while on a local scale, few streets have expressive value.

Conclusions

The verticalization process is one of the responsible for the transformation of the urban landscape and is part of a capitalist strategy for profit on urban land.

In turn, the urban land value is highly influenced by its location into the urban space, especially considering the proximity to the center, services, businesses and its urban infrastructure.

In this context, a configurational analysis can help explain the logical of location within the urban space. Thus, the Theory of Space Syntax helped identify the configurational characteristics of streets with buildings in the center of Florianópolis.

Through the analysis it was identified that within the central area of the city of Florianópolis, apartment buildings are located on streets with high global and local integration, that is, the other areas are near the city. As to the measure of choice, implantation occurs preferentially in streets that have medium to high level on a local scale, therefore, these streets are not part of the shortest paths to other parts of the city, but within the center itself.

In other words, the preference deployment occurs in streets that make its central location and easy access to many points of the city location, however, prioritize relatively quiet pathways outside the access roads to other places outside the center.

Typological atlases of block and block-face

Alice Vialard

E-mail: alicevial@gmail.com.

Abstract. *The classification of blocks and block-faces according to several morphological characteristics is used in this paper as a basis for assessing urban form. Classification aggregates discrete data into categories which can subsequently become associated with specific considerations, requirements or solutions regarding city planning and design (Steadman, Bruhns et al. 2000). The issue, then, is to present similarities, co-variations or contingencies in a meaningful and legible manner so that the resulting typology of urban conditions can support planning or design actions. The intent is to represent and characterize urban units according to numerical profiles and to group them into clusters, using the k-means method (Gil, Beirão et al. 2012). As a second step, clusters are depicted on maps to produce typological atlases. They serve to assess existing urban conditions or test future urban conditions. Two typological atlases are proposed. The first concerns the morphology of blocks based on shape and size; the second concerns block-faces as the interface between street and building, coalescing external and internal loads. Syntactic measures such as metric and directional reach (Peponis, Bafna et al. 2008) characterise the external load exercised by the street system and morphological measures such as setbacks and building frontages (Talen 2005; Oliveira 2013) represent the internal load exerted by buildings. The typological atlases help visualize the prevailing building and street patterns and facilitate the evaluation of urban conditions so as to distinguish between saturated areas and areas with greater potential for future development.*

Key Words: *Block-face; typological atlas; block morphology; metric reach.*

Introduction

The morphology of our cities entails fundamental problems but also, when studied carefully, hints for their solutions. The form of North American cities, particularly as it has accrued since the 60s, has been characterized principally by ‘urban sprawl’. Studies of the configuration of sprawl show the incompatibility between our understanding of irregular forms and the tools proposed to measure it (Scheer, 2001). Furthermore, a study that compared the urban form of Barcelona and Atlanta has shown that measures that are relevant for a regular and dense city cannot be applied to a sprawling city (Bertaud, 2004). Solutions that deal with sprawl should be able to accommodate changes as part of the inward and outward growth of cities, without detriment to the large-scale functioning structure. Of particular interest is the question of whether an area developed as a suburb can get more densely urbanized over time, and, if it can, which particular suburban sites are good candidates for the initial steps towards denser urbanization.

This paper proposes a way to measure and assess existing urban form in the context of North American sprawling cities as a basis to provide more targeted and appropriate solutions, which are a step towards sustainability. For this purpose, a systematic way of assessing urban form has been developed, taking into account selected syntactical and morphological properties used in previous studies of cities. Part of the work has been to adapt some of existing measures for the study of irregular forms. However, the main contribution of this proposed framework is to link these properties to a single morphological unit, the block-face, as the interface between street and building that is expected to provide a more comprehensive account of the existing conditions.

The block-face as unit of analysis

The methodology builds upon a research tradition of analytical and quantitative studies of urban layout developed in the fields of morphology and space syntax. It raises two questions regarding the unit of analysis and the measures of built environment. Studies in urban morphology typically look at the interactions between urban block size and shape, and patterns of buildings. Typically, however, the impact of the larger scale syntax of street network is not taken into account. On the other hand, studies in space syntax have looked at the interaction between street connectivity, land use and development density, but have not specifically addressed the geometry of urban blocks.

Linking buildings to streets and blocks to buildings

Bridging two fields, recent studies have shown correlations between building density and street connectivity. While space syntax is typically concerned with accessibility, Marcus (2010) has proposed the concept of “spatial capital” to relate street accessibility, building density and population diversity. Direct street accessibility is an essential component of building density in relation to street life which lends itself to promote a continuous built environment along streets. To integrate the notion of accessible building density is to look at how the street relates to buildings physically, by measuring frontage and setbacks.

Looking at building configurations, Berghauser Pont and Haupt (2002, 2010) establish a strong relationship between block dimensions and building configurations and building functions. The diversity of building configurations within a block is captured in a matrix called ‘spacemate’ that associates block area, open space area, ground floor area and total floor area with different types of developments. This study highlights the impact of size of urban block to building density, but does not fully integrate the impact of the block boundary, which is made by the streets. The area of the street is considered to be part of the non-built space, and it is not strongly integrated into the space matrix. To complement these existing measures of block size, measures of shape based on block periphery are proposed to link blocks to streets.

The block-face

Recent studies have started to link building configurations and street networks. In a study of New York, Oliveira (2013) uses streets, plots and buildings as morphological units to link syntactic properties of streets to the morphology of buildings (frontage, height), as well as to land-uses. This in-depth and comprehensive study limits itself to relatively few streets. Using a GIS platform, it is possible to develop a more systematic linkage between the syntactic properties of streets and building morphology.

In the context of sprawling city form, the potential of sites to accommodate future development should to be assessed in terms of the balance between local and global access, as determined by the conditions at the perimeter of the block and available land as determined by block size, shape and existing building footprints. The block-face emerges as the morphological element that naturally associates the properties of the street network and the properties of buildings. The block-face is the element that belongs to both the street and the building and, as such, can capture variations along a street or between different faces of a block. By looking for systematic relationships between buildings and streets, there is a clearer understanding on how they associate or dissociate. As such, they can affect the future of cities by constraining the potential forms of future development.

Figure 1. Number of block-faces based on road segment. The distinction between (b) and (e) is the source of the pressure on the boundary: external (b) or internal (e). The variation between number of road segments and number of faces happens when there are internal road segments: dead-ends (e) or internal street (f). Blocks (c) and (d) are cases of block partially or fully contained within another block.

The block-face, as morphological unit, has been used in only few urban morphological studies (Purciel, Neckerman et al., 2009). The distinction between collecting data at the block level or the block-face is that the latter includes the street as a unit of analysis. Figure 1 illustrates the different translations from road segments to block-faces. The number of faces per block corresponds to the number of road segments associated to a block with adjustment for internal road segments.

Measures

The balance between street properties and building properties defines the value of blocks and block-faces. This section presents a set of attributes related first to street layout and second to building footprints. Once defined, the measures of the built environment are transferred as “load” onto the block-face. There are two distinct kinds of loads, the internal load that measures density and continuity of buildings configurations and the external load that includes the connectivity and the accessibility of the street network. Figure 2 summarizes the relationships of each morphological unit to their syntactic and morphological properties and their measures.

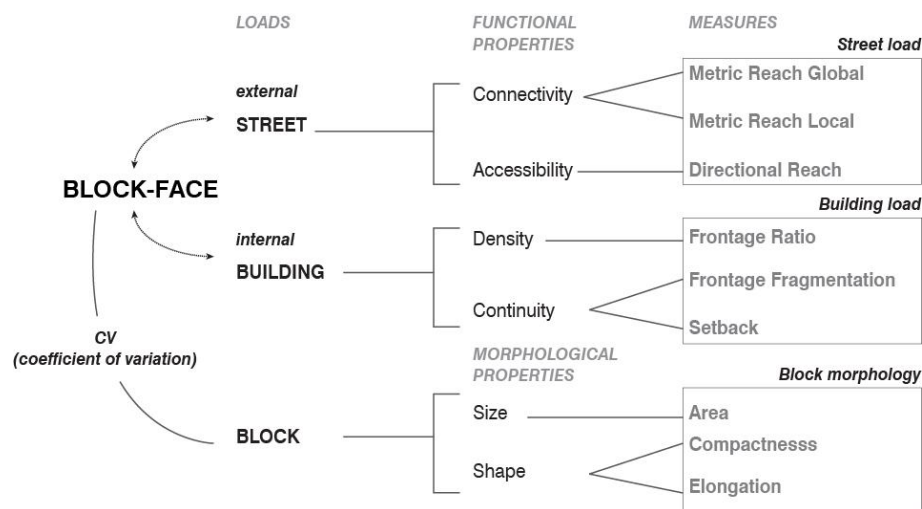

Figure 2. The relationships of morphological units, their syntactic and morphological properties and their measures.

Internal load - Buildings

Because the emphasis is on the density of the built environment along a street, the selected measures of the internal load define the relationship of building to the block boundary. This internal load expresses the density of construction in a given area, therefore, it implicitly relates to the potential for further development or to the saturation of the urban fabric. The location of buildings in the center or on the edge of the block determines the degree of enclosure or openness of the block. For a passer-by, the degree of “enclosure” of the block is characterized by the continuity or the interruption of facades along the streets: in other words, the “built frontage”.

Built frontage is made of the lines of the building footprint that are within a given distance from the block-face. Talen (2005) draws the limit at 9-14 meters in the interior of the block from the street for the sense of enclosure to be effectively present. In the case of Atlanta, the chosen distances are 15 meters from the boundary of the block (figure 3-1). The frontage ratio of a block-face is the percentage of its length that is built. The continuity of the frontage is captured by frontage fragmentation, which is the number of building fronts that makes the frontage and tells how fragmented the experience is for the passer-by.

The third measure is the setback, which is the distance from the limit of the lot and the street to the first line of the building footprint towards the center of the block. In this sample, setbacks are represented by radials. Radial setback indicates the ratio of “in front of the buildings” length and the “behind the building façade” length as one moves from the perimeter to the block center (figure 3-2).

External load - Streets

The second set of measures focuses on the characteristics of street layout, the external load. Street performance is principally linked to accessibility and connectivity. The connectivity of a street layout is defined by the amount of street length available within a set reach. At the urban scale, the metric distance and topological distance are incorporated in the measure of metric reach and directional reach (Peponis, Allen et al., 2007). Parametric thresholds are used to distinguish local from global reach. Each reach measure records a different affordance of the street segment. It is then transferred from the street segment to the two block-faces associated with that road segment.

Metric reach characterizes street density and street connectivity. It measures the total linear distance in miles that is available for someone departing from the middle of a road segment and “walking” a given distance in every direction (Peponis, Bafna et al., 2008)²¹. The given distance is called radius. Variations in the radius length capture either local street density, using, for example, a radius of 0.17 mile (270m), or global street density with radius of 5 miles (8km). Metric reach provides a measure of “potential”, of how much of the urban fabric is available nearby. It quantifies in length the range of nearby opportunities provided by the street network. To some degree, metric reach captures availability of alternative routes, or street connectivity. A metric reach value is assigned to each road segment to characterize block-face. High values demonstrate high density and therefore high local connectivity.

Directional reach records the total length of streets available from a street segment within a set number of changes of direction. What counts as a change of direction is specified using a threshold angle. In this study an angle greater than 10 degrees is considered a turn. Directional reach can be analyzed using different numbers of turns. Directional reach at 0 direction change

²¹ The details of their computation in the ArcView GIS platform is discussed in Peponis, J., D. Allen, et al. (2007). *Measuring the Configuration of Street Networks*. 6th International Space Syntax Symposium, Istanbul Technical University, Cenkler, Istanbul

depicts the “straightness” of the urban fabric locally. It is associated with the legibility of the urban structure. This is the only measure that does not take density into account; it is the simplest configurational measure. Other measures of connectivity and density exist, but these two are selected because they are associated with the street segment. The last set of measures relates to the design of blocks and their geometry.

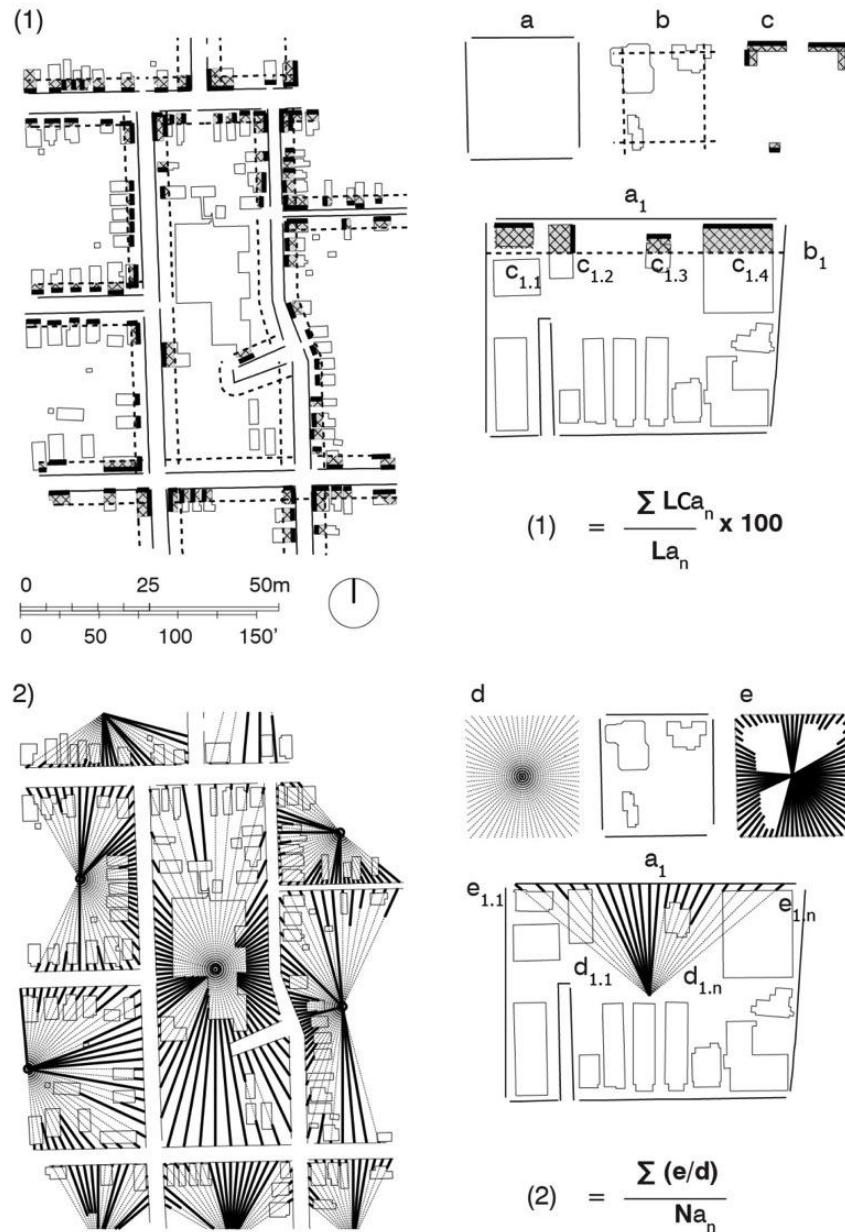

Figure 3. Frontage Ratio (1) is the ratio of the sum of the length of building frontage (c) that are included in the 10 meters buffer zone of that block-face (b) by the length of the block-face length (a). Block-face setback (2) is the average ratio of the length of the radial. Frontage Fragmentation (3) is the number of building frontage included in the 15 meters buffer zone.

Morphology of Blocks: relate linear dimension to properties of street and building configurations

The relationship of block-faces to a block resides in the morphology of the block and its capacity to distinguish its sides depending on which street a side is facing. Geometrical shapes can be measured in several ways, and the selected measures describe two aspects of a block: the periphery, which is in contact with the street, and its internal metric depth, which provides a framework for the location and size of building footprints.

Block size can be described by its area or by linear dimensions. Dimensions describing the overall proportions of block at the periphery are referred to as “width”. Average length, the length of the block perimeter divided by the number of block-faces, and segment length, the length of the street centreline between two intersections, are computed to characterize block width. Dimensions from center to perimeter are referred to as “depth”. They describe internal properties of blocks: the longest axis²² or maximum span is the distance between the furthest points on the perimeter, and the radial depth is the average distance from centroid to perimeter.

Other dimensions of block morphology relative to shape are the deformation of the block boundary and the proportions of the block. Deformation can be measured by the distortion of the perimeter or by variations in depth. To compute the distortions of the boundary, two shape indexes are presented and used to describe the block stock in Atlanta: square compactness and elongation. According to Colaninno, Cladera et al. (2011), the shape indexes based on the ratio perimeter-area (square compactness) and based on the longest axis (elongation) are both indicators of the “complexity” of a shape. Square compactness better describes the boundary and elongation better defines proportions.

Description of Atlanta stock

These measures become the basis for quantifying and building a profile of the blocks in a city. In this particular case, Atlanta is chosen to exemplify sprawling city form. Table 1 summarizes values and ranges of values for measures of street load, building load and block morphology.

Mapping

Figure 4 illustrates two ways of looking at the city of Atlanta based on the most recurrent type of block morphology. The first profile of Atlanta that shows the most recurrent type of block dimensions is established based on the selected dimensions for width and depth. To make up the profile, blocks with a radial depth between 43 and 93 meters and with an average face length between 58 and 122 meters are selected. Only 1071 blocks match the two requirements (figure 4-1). While the ranges selected described half of the sample when considered one at a time, the final selection based on both measures encompasses only a quarter of the blocks. These belong to the small-medium category, with an average size of 1.3 hectares.

²² To measure internal dimensions, except the radial depth, we use the Shape Metrics Tool developed by Jason Parent and available online [http://clear.uconn.edu/tools/Shape_Metrics/index.htm]. It calculates the longest axis, the girth and other measures that will be needed to compute index of compactness. The tool is a Python script that runs out of ArcToolbox in ArcGIS 9.3. It requires a polygon as an input. The measures are explained in detailed in a published article: Angel, S., J. Parent, et al. (2009). "Ten compactness properties of circles: Measuring shape in geography." *Canadian Geographer/Le Géographe canadien* 54(4): 441-461.

Table 1. Summary of values and ranges for all selected measures in the city of Atlanta.

Block-face (n= 29750)		MEAN	MEDIAN	QUARTILES	ALL
Street load					
Metric Reach 0.17	<i>mile</i>	0.91	0.86	0.63-1.15	0-3.1
Metric Reach 5	<i>mile</i>	735	776	602-880	210-980
Directional Reach 0dc	<i>mile</i>	0.5	0.24	0.1-0.56	0-27.5
<i>Building load</i>					
Frontage Ratio (20m)	<i>percentage</i>	26.8	22.8	0-46	0-141
Setback	<i>percentage</i>	46.7	41.8	27-64	0-100
Frontage Fragmentation	<i>n</i>	2.9	2	0-4	0-46
<i>Block (n= 4028)</i>					
<i>Block morphology</i>					
Area	<i>hectares</i>	6.15	2.01	1.1-4.3	0-503
Average Length*	<i>meters</i>	130	109	78-158	11.6-2046
Segment Length	<i>meters</i>	173	131	85-212	7-2585
Maximum Span	<i>meters</i>	339	239	168-386	8-4107
Radial Depth*	<i>meters</i>	91	74	56-103	2.7-657
Square compactness	<i>0-1.3</i>	0.78	0.84	0.65-0.95	0.06-1.24
Elongation	<i>0-1</i>	0.66	0.68	0.59-0.75	0.2-0.94
Number of block-faces		6.4	5	4-6	1-136

**averaged dimensions*

The second profile of Atlanta blocks is based on block shape. It is made of blocks with square compactness between 0.8 and 1.01 and an elongation index between 0.66 and 0.8. Only 1173 blocks match the two requirements (figure 4-2). Although still small, this profile includes a wider range of block sizes, with an average value of 2.1 varying between 0.01 and 52 hectares, compared to the profile based on dimensions alone. The two maps imply two different principles of urban blocks in Atlanta, but they both show that the combination of different measures to describe a typical block creates much smaller better-specified categories.

Clustering and visualization

Atlanta embeds a variety of urban forms that range from traditional urbanism on a gridiron to extreme forms of sprawl. Predictably, the local and global connectivity of the urban form varies widely in Atlanta. Furthermore, Atlanta is comprised of urban forms that have not yet reached their full potential in terms of building density. In these currently sprawling patterns, there is room for future density and street connectivity to increase. Thus, it is useful to determine how to measure their potential for transformation and which physical characteristics are more conducive to changes in block subdivision and street connectivity.

The mathematical classification of urban and built form allows for the precise identification of commonalities and differences between designs. Classification is a way to group elements with similar characteristics so as to reveal their potential in terms of evolution, function and performance. The classification of designs is traditionally based on visual and formal resemblances that are identified to propose types. The designer, who then uses the types, knows that they embed certain properties. The role of quantification and formal analysis is to structure the exploration of possibilities given that geometry and topology impose their own limitations upon urban and built form. It is also important to note that the typology presented is not final.

Different emphases produce different types based on aspects of morphological properties, syntactic properties or a combination of both.

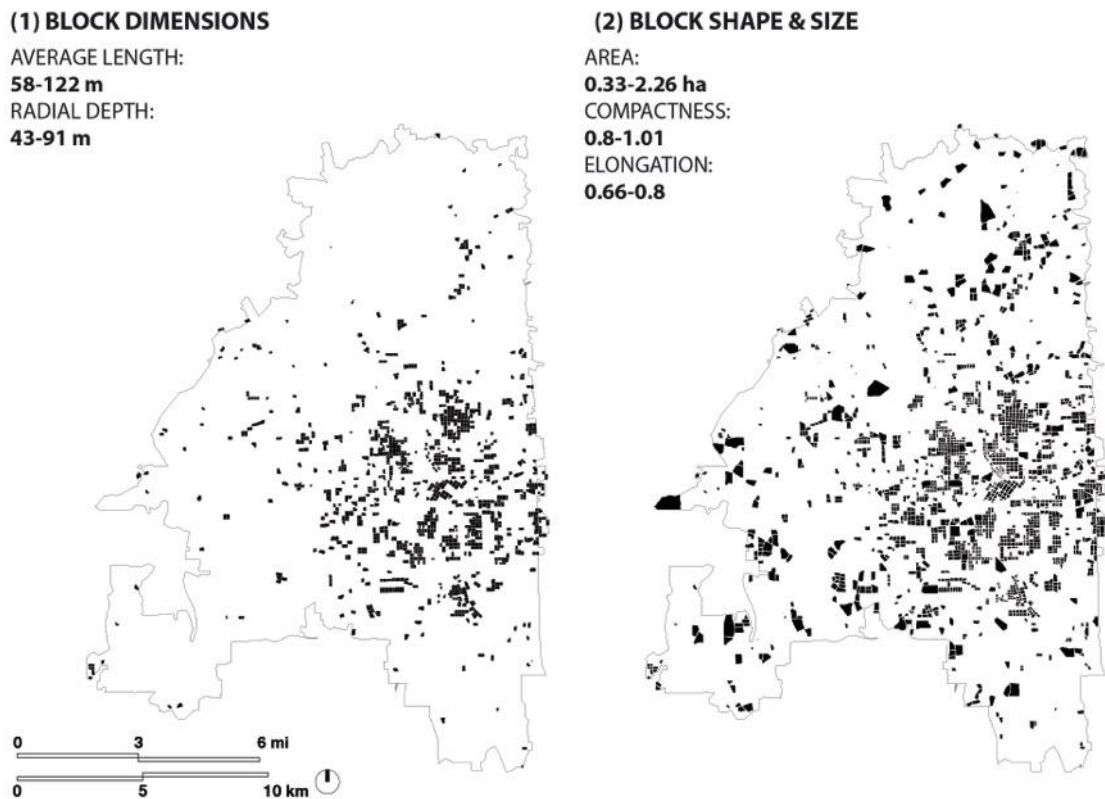

Figure 4. Blocks representative of Atlanta based on their radial depth and average length dimensions. They represent the compact half range (n= 1071) (1). Blocks representative of Atlanta based on their area, square compactness and elongation. They represent the compact half range (n= 1173) (2).

Clusters (k-means)

The classification of neighborhoods has been used to evaluate the efficiency of urban design policies (Song and Knaap 2007). Song and Knaap aggregate a set of measures into eight factors that serve as inputs for k-means clustering. Cluster analysis is used in order to produce classifications of urban form (Gil, Beirão et al. 2012). Other authors characterize urban structure by using data training and discriminant analysis algorithms to produce classifications based on the shape and configuration of buildings (Steiniger, Lange et al. 2008). The most complete and automated computational classification of urban structure taking into account building footprints and block shapes deals with Barcelona (Colaninno, Cladera et al. 2011). The authors train the model by using established historical periodization. They subsequently integrate the structure of the street network into the analysis. A thorough review of pattern classification methods by Duda and Hart (1996), suggests that k-means clustering tends to divide a set of objects into homogeneous groups with no preconceived information about the group structure of the data.

The k-means clustering organizes blocks into clusters that share common properties. The goal is to create clusters that show statistical and numerical evidence of similar patterns. Several parameters can be given as input and the data is partitioned according to the distance of each entry to the different means. With k-means clustering the data are partitioned into a number k of clusters, determined by the user.

Morphology of Block clustering

A first clustering of the Atlanta blocks by their morphological properties is established as follows. Three morphological factors are selected to characterize the size (area) and the shape of blocks (square compactness and elongation). After several tests, the number of clusters was fixed to eight: fewer clusters did not provide enough discrimination and more clusters created too many classes with too few elements, and quite small variations of values between clusters. The different clusters are illustrated in figure 5.

Regarding block area, k-means clustering partitions the blocks into groups ranging from small-medium blocks to mega blocks, the blocks larger than one million square meters. Regarding square compactness, which is sensitive to the shape of the block boundary, clusters highlight the range from regular to convoluted blocks. Finally, regarding elongation, which describes the overall span of the block shape, clusters distinguish between consolidated/compact, elongated and narrow blocks.

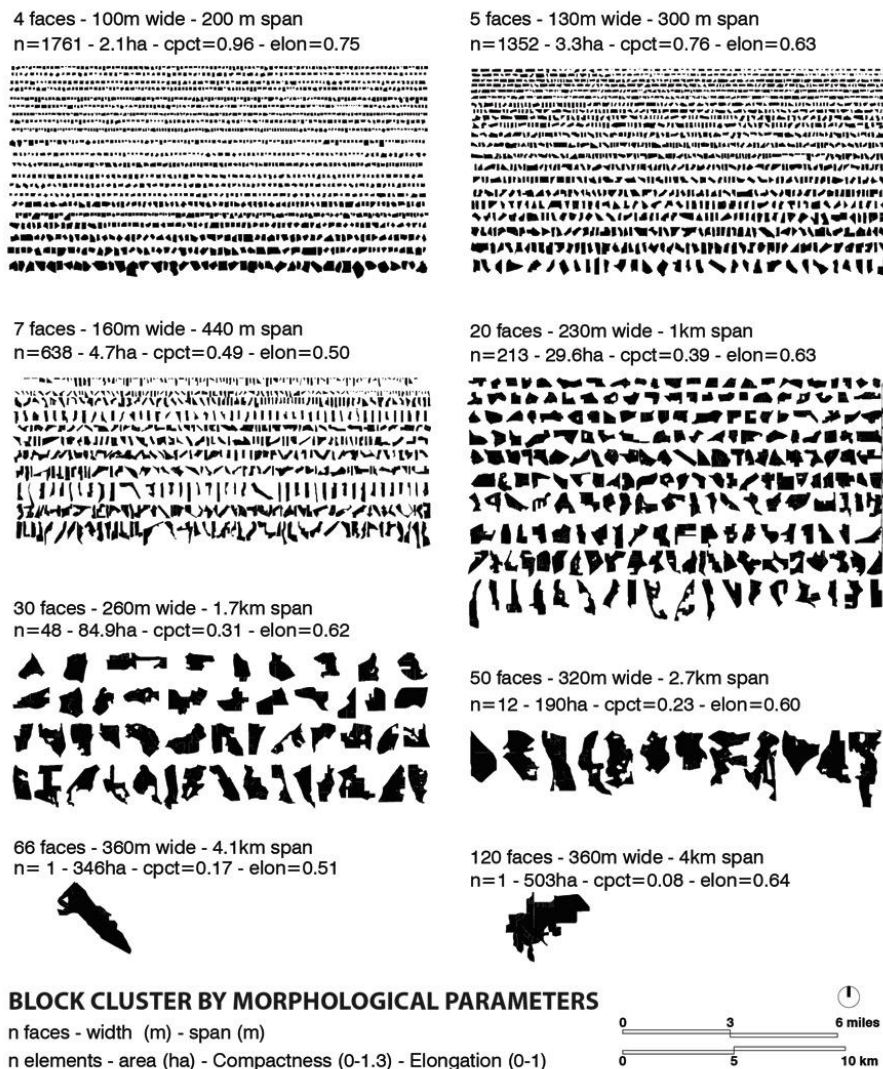

Figure 5. Eight clusters from the k-mean method based on area, square compactness and elongation: table with mean values. For each cluster, the mean number of block-faces, average length (width) and longest axis (span) are reported in meters.

This classification of blocks by morphological characteristics provides a first step towards the assessment of the existing state of the urban fabric. Other design characteristics are associated with each cluster. For example, the average dimensions of span (longest axis), depth and width are given as well as the average number of block-faces.

Mapping Syntactic clusters – characterisation of neighbourhoods

For the purpose of understanding the effect of different types of external loads on the formation of neighborhoods, urban blocks are clustered to depict configurations and associations in their urban contexts according to distance from the center, the density or the linearity of their association, their isolation and the complexity of their boundary. The clustering method by k-means divides the sample into 8 clusters according to the external load measures: local connectivity, measured by metric reach radius 0.17 mile (274m); global connectivity, measured by metric reach radius 5 miles (8km); the regularity of the grid, measured by the directional reach value for 0 direction changes, and the regularity of the grid, measured by the number of block faces, which is sensitive to the number of internally and externally oriented T-junctions along the block periphery.

Figure 6 illustrates the clustering of blocks according to syntactic properties of the adjacent streets and their location on the map. Block clusters tend to form patterns of aggregation that visualize traditional type of neighborhood as well as less recognizable ones. In the grid type, homogeneous and compact neighborhoods are split into three categories: small compact neighborhoods made of regular blocks centrally located, such as in “*Downtown Atlanta*” (figure 6-a); compact neighborhoods with a more organic structure like “*Ansley Park*”, with its curvilinear streets based on Olmsted-type principles (figure 6-b) and fairly compact neighborhoods at the periphery of the sample (figure 6-c). These last two clusters have the most numerous elements; their difference is essentially in their location; within some 4-5 miles (6.4-8km) from the city center (figure 6-b) and others located beyond the 5 miles (8km) boundary (figure 6-c).

The linear distribution of pattern relates to neighborhoods with a high mean directional reach. These clusters represent blocks attached to a major street that is long and straight. These are neighborhoods that developed along a major axis such ‘*North Avenue*’ (figure 6-d) or ‘*Sylvan Road-Joseph Lowery Blvd*’ (figure 6-e). The other clusters depict association of large, complex pattern blocks with a high number of block-faces. The pattern of blocks is interrupted by large gaps that create large discontinuity. Adjacent blocks only share a small proportion of their perimeter. They are very large blocks with normal-medium global and local reach and directional reach. Finally, isolates (figure 6-h) have the highest number of faces and the lowest global mean reach and directional reach.

From a connectivity standpoint, Atlanta presents fairly discrete neighborhoods with very few connections between them. New typologies arise linked to properties of long straight lines or to a very complex system of bounding streets. Reciprocally, morphologies of neighbourhoods are associated with syntactical characteristics.

Block-face clustering and mapping

The urban form of Atlanta can be characterized as diverse. While Atlanta is made of a majority of small and fairly regular blocks, as shown in the first profile, the extremely large blocks participate fully as elements of discontinuity. The discontinuity of the urban fabric is one of the main characteristics of the overall urbanism of Atlanta. The second characteristic is that building configurations in Atlanta are characterized by very deep setbacks that do not participate in defining the continuity of city form. The two main issues are where to implement new development to create a sense of continuity and how to use the existing potential carried by the street network. Density should be increased for block-faces with high connectivity and buildings should be located as to create a continuous frontage.

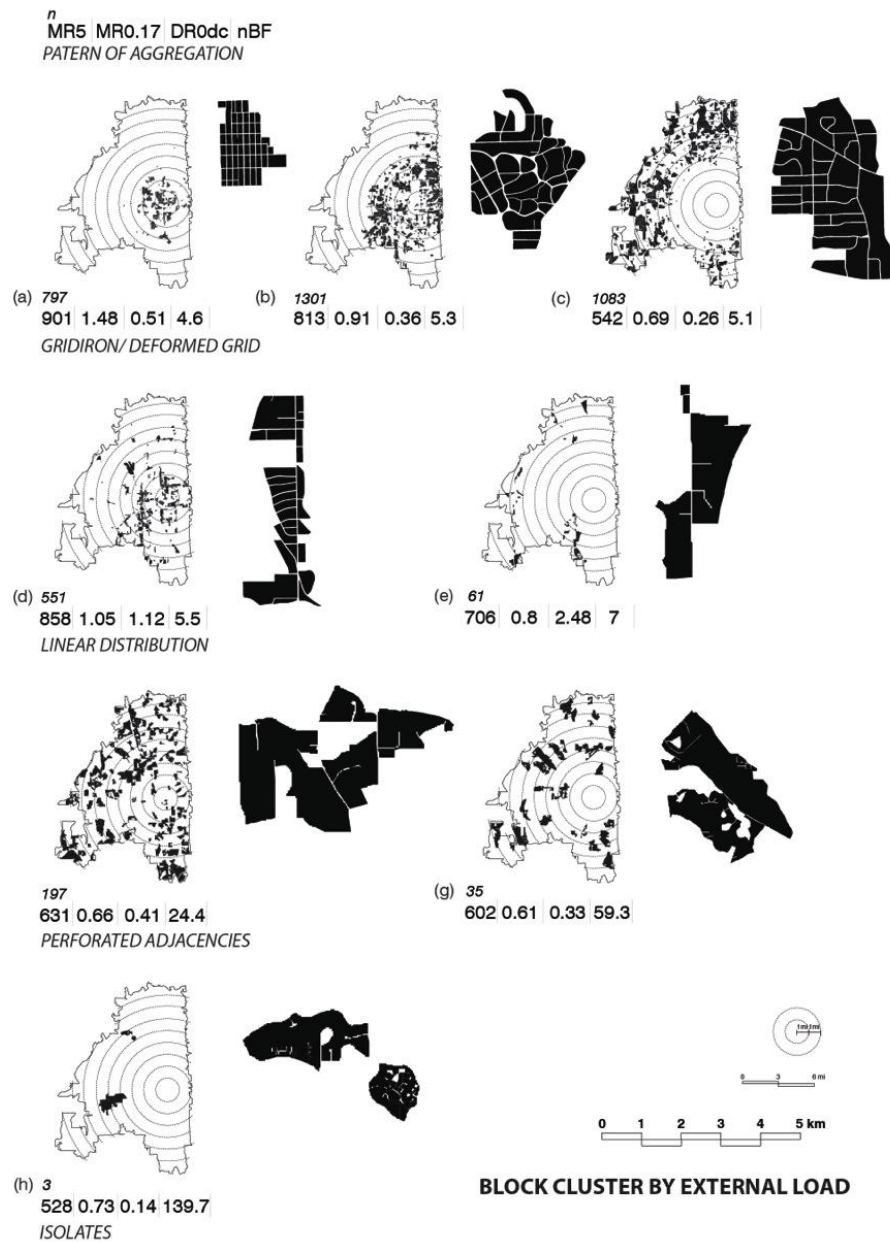

Figure 6. Clusters based on external load. The number of blocks (*n*) is reported for each cluster as well as the metric reach radii 5 miles (MR5) and 0.17 mile (MR0.17), the directional reach without change of direction (DR0dc) and finally the number of block-faces (nBF).

A block-face is the link between the external characteristics of the road structure and the internal pressure of building load. The combination of all these parameters provides a framework for comparing and classifying block-faces. The k-means method previously used is applied once more. Three parameters for the external load and three parameters for the internal load are included in the calculation. The building load is represented with the amount of frontage at 20 meters from the centerline, its fragmentation and the presence of setbacks. The external load encompasses the global metric reach with a 5 miles radius (8km), the local metric reach with a 0.17 mile radius (274m) and, finally, the straightness of the road structure with the directional reach with no change of direction.

Table 2. The mean values for 8 Clusters of block-faces according to three parameters of building load and three parameters of street load. Frontage fragmentation [F20F] and ratio [F20R] at 20 meters and setback ratio [SK] account for the building load. Reaches with metric reach 5 miles [MR5] and 0.17 mile [MR0.17], with directional reach 0 direction change [DR0dc] account for the street load.

Cluster	STREET LOAD			BUIDLING LOAD			
	MR 5 (mi)	MR0.17(mi)	DR0dc (mi)	SK (%)	F20R (%)	F20F (n)	# block-faces
1	479	0.45	26.42	92.9	0.00	0.00	4
3	53	0.50	12.28	77.1	1.70	0.23	22
2	543	0.64	0.29	80.9	15.15	1.72	4373
4	588	0.70	0.24	31.6	41.87	4.10	7127
6	867	1.12	0.46	74.9	20.26	1.45	5269
7	869	1.19	0.48	25.6	70.86	4.26	8473
8	811	0.99	3.11	46.7	34.37	2.49	1296
5	728	0.67	0.28	30.7	67.55	13.56	3006

Several clusters have similar street loads parameters and very different building load and vice versa. Table 2 pairs the clusters with similar characteristics of either building or street loads: clusters 1 and 3, clusters 2 and 4, clusters 6 and 7. Cluster 1 includes empty block-faces near highways. They have very high directional reach but very low connectivity and are empty. Cluster 3 is a slight variation of cluster 1 with low building loads. Block-faces have plenty of available space for new buildings but are not connected well to their surroundings. Cluster 2 includes block faces with almost no building on their edges, but with low setbacks where built. Cluster 4 includes block-faces that are fairly well built on the edge, with building footprints also covering the interior so that no additional building can easily be added.

Cluster 7 represents the best performing block-faces, they are highly connected locally and globally, they are fairly accessible, the setbacks are minimum (quarter), they are highly built on their edge (70 percent) with a reasonable fragmentation (4 to 5 building footprints on average). They are functioning well. Cluster 6 has similar behavior for connectivity and accessibility but their building footprint load is very low: only 20 percent of the frontage is built by 1 or 2 building footprints, setbacks indicate lack of buildings with a 75 percent value on average. In the similar location but more empty of footprints, cluster 6 can be seen as containing blocks which are at an earlier stage of development compared to those in cluster 7.

Cluster 8 is average on every level, but with higher values on connectivity and low values on building load with only 35 percent built and fairly low number of building footprints (2 to 3). These block-faces are located near long straight lines that are not highways. They have a very good potential based on their existing connectivity and accessibility. Cluster 5 seems to represent the suburban type of block-face with lots of building footprints (13.6) and high frontage (68 percent): single-family houses. Block faces in this cluster are fairly well connected globally, but not performing as well locally.

To illustrate the different types of block-faces, an example of streets and blocks is provided in locations with large irregular blocks with diversified conditions on the boundary (figure 7). The example shows the block that accommodates the Atlanta City Water Works Reservoir II with

some surroundings blocks. It shows six distinctive types of block-faces. The north side is made of block-faces type 4. They are characterized by low global or local connectivity and medium straightness associated with a fairly small amount of frontage associated to deep setbacks (half way between the center and the boundary) with few building footprints. There is little to be done to improve the existing conditions. In block-face type 8, located on the east side of the block, similar building configurations exist but in a very high connectivity and straightness context. The east side of the block is bordered by Northside drive, which gives lots of potential for buildings that need connectivity and accessibility, but the existing configuration of buildings needs to be improved. The south boundary is fairly unbuilt with block-faces type 3 and is fairly well connected. More buildings could be added. However in that specific example, half of the southern boundary is bordered by the reservoir. The same condition exists for the block-face type 2 but as a cul-de-sac, it is less accessible and less connected.

In summary, some of the clusters are context dependent: clusters 2 and 6 are concentrated in specific regions, and cluster 8 is linked to specific streets. On the other hand, different building configurations exist for similar street characteristics. The example of the large block (figure 7) showed that a single block can have variations on its edges to accommodate different building configurations. The ability of some blocks to create different conditions along their edge carries an interest for creating diversity.

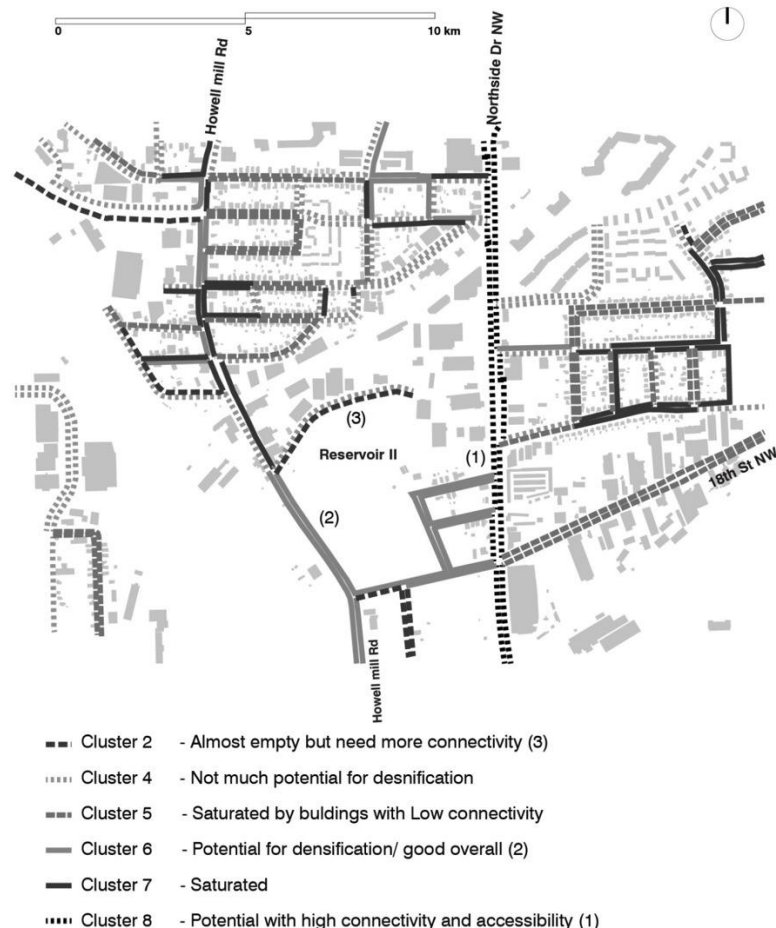

Figure 7. Example of different block-face types around a fairly large block (Atlanta City Water Works Reservoir 2) that illustrates clusters 2, 4, 6 and 8. The immediate surroundings include also clusters 5 and 7.

Conclusion

The proposed framework to understand the behavior of existing block-faces concerning building and street loads has shown that block-faces can have different levels of densification. However, only some block-faces have the flexibility to accommodate changes, particularly for addition of buildings. The analysis of block-faces has facilitated explorations of the significance of streets in relation to buildings. Streets can now be defined as made of two sides; thus, they link two possibly different conditions emerging from the two blocks they are in contact with. Streets also link adjoining blocks along their length. The context is included in the assessment of block-face.

This article has shed light on some purely morphological relationships. It has also proposed to bring block-faces into focus as fundamental to our understanding of city form. In doing so it also proposes ways in which the interface between architectural and urban design can be visualized. Block-faces have emerged as the boundary and interface at which the syntax of street networks and the syntax of built form interact.

This work contributes to the assessment of existing cities, specifically to the identification of locations with greater potential for development based on good connectivity and good availability of development land at the edge and also in the interior of blocks. The work also contributes to the assessment of the potential of individual properties considered for real estate development.

Analysis and modeling of spatial changes: Identification and quantification of urban growth in Florianópolis-SC

Raquel Weiss, Alina Gonçalves Santiago

Post-Graduation Program of Architecture and Urbanism Department, Federal University of Santa Catarina. E-mail: rwarqui@hotmail.com, alinagsantiago@hotmail.com.

Abstract. *The urbanization process is one of the most remarkable manifestations of human actions on space, highlighted by the progressive population growth in urban centers. Such growth is what makes cities big and complex structures, representing the peak of the way of life, appropriations, transformations and manifestations that humankind is capable of imposing, be them economic, social, or environmental. Thus, scenarios with a tangled, intrinsic and dynamic physical and territorial structure emerge, reflecting the changes in the morphology and functionality of such places, thus becoming urban spaces rather than rural areas. Among the trends in urban expansion, it can be highlighted urban sprawl, characterized by low density, fragmented, polynuclear, and often uncontrolled urban dispersion. Considering this, and taking as case study the city of Florianópolis-SC-Brazil, marked by the distribution of several urban nucleiconsolidated throughout its insular territory, the present study aims at understanding, identifying and quantifying the dynamics and spatial organizations of the city areas. In order to do so, spatial-temporal analyses of land use through photo interpretation in GIS platforms of representative spatial cutouts representing different existing urban morphologies have been conducted. Besides that, geoprocessing techniques and the use of spatial metrics are employed in the evaluation and classification of variables through numeral indicators. Thus, the mapping and quantification of the alterations represented by Human vs Space interaction throughout the analyzed period allows a better understanding and a higher accuracy of the spatial dynamic processes.*

Key Words: Urban morphology; spatial metrics; GIS, spatial-temporal analysis; urban sprawl.

Introduction

The cities have undergone considerable changes in recent decades due to urban growth. Progressive and intensified form, remains ongoing process of urbanization, leading to changes in land use, causing significant physical-territorial impacts, mainly related to urban morphology (Coelho et al., 2014, Borges et al., 2010). According to Deng et al. (2009) and Kong et al. (2012), urbanization is characterized as the most powerful and visible action of the force of man, which causes sudden changes in use and landscape patterns, to relate mainly the social and economic issues.

In this context, marked by the performance of the real estate market, the interests of society and public policy, is occurring a dispersed process of urbanization (*urban sprawl*) (Inostroza et al., 2013). Characterized by low density, spreading spatial patterns, configured for fragmented and discontinuous urban settlements, forming a polynuclear structure and highly dependent on the automobile, leading to significant environmental shocks (Herold et al., 2005, Costa and Silva, 2007, Bhatta et al., 2010, Aguilera et al., 2011, Thapa and Murayama, 2009, Yu and Ng, 2006, Tv et al., 2012, Aljoufie et al., 2013, Yu and Ng, 2007, Barredo and Demicheli, 2003).

In order to mitigate the impacts of urban sprawl, the monitoring of urban development by means of spatiotemporal information appears to be an important tool in the evaluation of transformations of the territory. Especially, in order to ensure the sustainability of cities in the future. The use of geotechnologies, which combines remote sensing and GIS techniques (Geographic Information System), is a valuable resource in the planning and construction of urban policies, it is possible to identify and understand the dynamics and shape of the urban growth process (Coelho et al., 2014, Borges et al., 2010, Deng et al., 2009).

Among the techniques for assessing the dynamics of urban land occupation, allowing the characterization and diagnosis of problems, has emerged the use of spatial metrics. These are adapted from related Landscape Ecology studies and shown to be an important geospatial tool.

Directed to studies of landscape and different ecosystems, especially the themes of forest and animal species, emerged from the 1980s (Moura, 2010b, Moura, 2010a, Liu et al., 2010, Li et al., 2005). It is configured on a system that studies the landscape from the perspective that it is formed by the heterogeneities of an interactive system, the formation of a mosaic of patches or fragments (Forman (1995), Lima and Rocha, 2011). From a system where there is a relationship between its components, allows the realization of assessments at different spatial and temporal scales, studying the composition and structure (Poletto and Metzger, 2012).

In this scenario, based on the methods of Landscape Ecology, have become the urban spatial metrics to urban studies. It is noted an interesting mechanism in knowledge area for the analysis of spatial and functional patterns. Through the generation of quantitative data and indices featuring urban space as the form, size, number and geographical dispersion of its constituents (Sundell-Turner and Rodewald 2008, Sanches and Ferreira 2008, Aguilera et al., 2011).

Thus, taking as a case study of the city of Florianópolis-SC, which is marked by the distribution of numerous consolidated urban centers along its island territory (Figure 1), this study aimed, from a spatial clipping, the Canasvieiras District to understand, identify and quantify the dynamics and spatial organizations of the areas.

Material and methods

Study Area

The District of Canasvieiras is located on the north coast of Santa Catarina island, 30 Km from the capital center. Its main highway access is SC 401. According to data from the CENSO (2010) has a population of 18,091, approximately 4.3% of the city's population and population density of 280.67. See Figure 1.

Figure 1. Localization Township Canasvieiras (source: Authors on Basemap Arcgis 10.1).

The local appears as major urban centers in Florianópolis, endowed with significant infrastructure and services. Constituted itself as one of the first centers of the island with bath-house function, thus having its process of urban growth intensified after 1950 when the Municipality begun work on parcels and deployment streets (Reis, 2012, Silva, 2000).

Thus, the choice of the spatial clipping area is due to its history of urban development, which resulted in the diversification of morphological structures. On one hand there they are significant areas with the urban mesh in “fish spine” format resulting from improper installment patches of lands well as the city growth along main roads. Moreover, the development of areas with a regular reticule, a factor that distinguishes them from other bath-houses areas of the city for its concentration and morphological structure.

Construction of the cartographic base

The work was based on the integration of historic images dated 1977, 1994 and 2013. Equipped with high spatial resolution, developed the mapping of urban areas through photointerpretation in GIS (Arcmap) interface, to identify the spatiotemporal dynamics. For Kong et al., (2012) to conduct studies that consider the territorial changes over time, combined with the remote sensing constitute an important basis for research and play a determining role in making diagnoses and planning proposals.

Application of spatial metrics

The ability to quantify the structure of the space is a prerequisite for studying the function and modification of urban dynamic (Forman, 1995; Herold et al. 2005, Li et al., 2011). This study, we used a series of spatial metrics to quantify and measure the urbanization process over 40 years, in order to understand the relationships between the spatial patterns, structures and processes of the urban District of Canasvieiras in relation to its urban fragments.

Thus were applied metrics in class level relative the spots area, shape complexity and distance from urban areas, based on other works by applying the metrics within the city such as Herold et al., 2005, Calegri et al., 2010, Muchailh et al., 2010, Yeh and Huang, 2009, Li, 2008).See

Table 1. Spatial metrics and description (source: Authors, 2014).

Spatial Metrics
NP - Number of patches
Total number of patches
TLA - Landscape area
Sum of areas of all patches class level
CA - Class area
Sum of areas of all patches belonging to a class
MPFD -Mean patch fractal dimension
Shape complexity
NNDist – Nearest neighbourhood distance
Distance to the nearest-neighboring patch of the same

Subsequently obtained the database relating to metrics, developed in an extension of Arcmap called Patch Analyst. Together, the development of graphics and tables to better elucidate the obtained information.

Finally, building mappings concerning measurements and indices identified by metrics with subsequent confrontations, explaining the changes in the respective analyzed periods.

Results

The formatting of the mappings and graphics contemplated 3 metrics in 3 distinct periods of spatiotemporal analysis, as follows: class area, mean patch fractal dimension and nearest neighborhood distance. All categorized 5 intervals.

CA- Class area

The 1970s represented the beginning of large investments in infrastructure in Florianópolis, especially works of implementation and better highways, especially paving the SC 401, as previously mentioned, the main access Canasvieiras District. Encouraged by national development policies, the study area followed the moment and began the process of implementing road and hence urban growth (Trindade, 2009). From the 1970s the District also began to consolidate as one of the main centers of interest to tourists, opportune by improving the SC 401, which enabled access to the beautiful bath-house characteristics (Santiago, 1995).

Thus, we realized the rootedness of 3 significant urban areas, as well as its conformation along the coastline (Figure 2), is characterized as the first function in nucleus with bath-house on the city. Therefore, urbanization spread along the continue pathways of margin.

The settlements, seen by the municipal government as major driver for tourism, have made great investments, as in that case, what distinguishes the area of studies of other urbanized areas of the island, the territorial organization resigned into a regular reticule (Reis, 2012), which will be further treated at work.

Until 1977 there were 8 urban patches, of which 3 have excelled containing from 34 to 163ha, representing 97% of the total urban area by cropping study. See Figure 2 and Table 2.

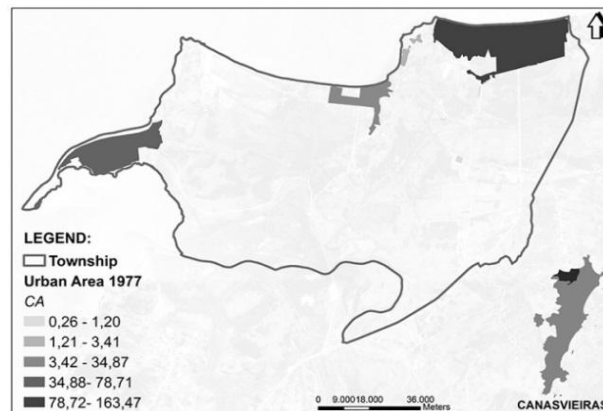

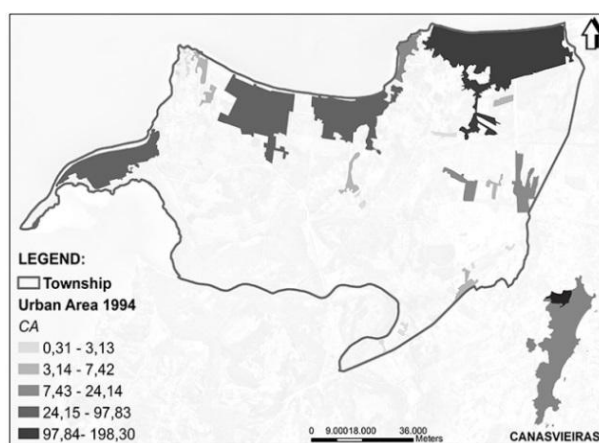

Figure 2. CA Urban area 1977 (source: Authors, 2014).

Regarding urban patches of decade 1994, an increase is found, totaling 23 areas (Figure 3). There was an increase of smaller patches, with until 7.42 ha representing about 69% of urban fragments, but representing less than 10% of urbanized area (Table 3). These conformed by the coast and along the SC 401. Urban development took place in the adjoining main highway, which is perceived similarity with other studies, indicating a global trend.

Major urban areas suffered major additions, by the consolidation of transformation of large farms in land from the real estate speculation and large urban-tourism undertaking arising from the financing of capitals representatives.

Table 2. CA Urban area 1977 (source: Authors, 2014).

Class	Patch	% cumulative	Area (ha)	% area
1,20	3	30,00%	2,10	1%
3,41	2	50,00%	5,34	2%
34,87	1	70,00%	34,87	12,26%
78,71	1	80,00%	78,71	27,67%
163,47	1	100,00%	163,47	57,46%

**Figure 3. CA Urban area 1994 (source: Authors, 2014).****Table 3. CA Urban area 1994 (source: Authors, 2014).**

Class	Patch	% cumulative	Area (ha)	% area
6,98	24	75,00%	34,87	4,63%
18,10	4	87,50%	59,75	7,93%
28,80	1	90,63%	28,80	3,82%
68,47	1	93,75%	68,47	9,09%
319,63	2	100,00%	561,57	74,53%

We emphasize the emergence of a new urban patch bordering the coast, conforming in 4 main areas that held approximately 445ha, or 82% of the city area (Figure 3 and Table 3).

Finishing the spatiotemporal exploration on the area of the patches, stood out conurbation of 2 zones conforming to the most fragmented urban area of the District (Figure 4). Together the 2 existing large areas totaled around 288ha, that is, 83.5% of urbanized area (Table 4). However, there was a noticeable intensification of smaller urban areas throughout the territory in an amount of 28 to 32, appearing with 87.5% of the total. From this, it was noticed the emergence of new and small urban centers distributed and represented 12.5% of the urbanized area (Table 4).

This process is possibly associated with a gradual fragment of properties configured for this process often clandestine and with peculiar characteristics. Other areas appeared and /or suffered increment, tangent SC 401, connected to a doubling from the 1990s. See Figure 4.

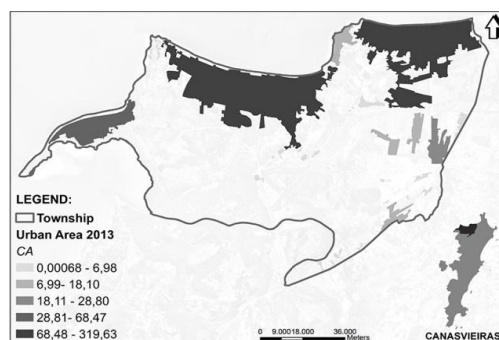

Figure 4. CA Urban area 2013 (source: Authors, 2014).

Table 4. CA Urban area 2013 (source: Authors, 2014).

Class	Patch	% cumulative	Area(ha)	% area
6,98	24	75,00%	34,87	4,63%
18,10	4	87,50%	59,75	7,93%
28,80	1	90,63%	28,80	3,82%
68,47	1	93,75%	68,47	9,09%
319,63	2	100,00%	561,57	74,53%

Thus, from Table 5 was possible to see the changes that occurred over 40 years. Initially the clipping study consisted of 8 urban patches, increasing significantly in 1994 and successively in 2013, though to a lesser extent. Concomitantly, there was a progressive increase in total urban area of the District over the analyzed period, showing the trend in Brazil and the world, mainly, indicating a population with urban profile.

From 1977 to 1994 there was a total increase of urban district, which reflected the intense process that happened from then on throughout the city, encouraged by the idea of development and implementation of infrastructure facing the roads. From 1994 to 2013, there were similar increases in area, together with the number of urban patches, but in smaller quantities, therefore the fusion of some urban areas.

Results that were reflected in the average size of the patches, where the first period was 3 representative urban patches of a smaller universe, which implied a higher average. In later years it was noted the decrease in the average due to the increase in the number of fragments, but with smaller standards of areas. This resulted in increased distribution of small urban locations, combined with the expansion process of existing areas. According to Moura (2010a) minor patches tend to have poor stability and was therefore subjected to greater dynamic, that is, modifications of urban growth processes.

Table 5. Spatiotemporal analysis and metrics (source: Authors, 2014).

Urban typologies on Canasvieiras District

Currently, Canasvieiras District is characterized by having two distinct models of parceling and urban grid. Differentiating itself from other bath-house areas of Florianópolis, influenced by tourism growth and together with large investments, land subdivision entered a formal order. The settlements that are tangent to the margin have cross line urban mesh, associated with legal encumbrances. This typology is in 3 principal patches in the mapping of 2013, just offshore, marked from the beginning of its creation from the years 1950/1960 and has suffered successive implementation processes. Figure 5.

However, there are areas with an urban morphology like "fish spine", with a discontinuous and irregular grid (Figure 6).

According to Reis (2002) this urban growth is associated with the conversion of large tracts of land before rural, in fragment urban portions, without any urban strategy set. Process which is set along roads that made up the route of the existing agrarian structure, characterized by both these cool systematization as illegal.

Figure 5. Regular grid (source: Authors, 2014).

Figure 6. Irregular grid (source: Authors, 2014).

MPFD-Mean patch fractal dimension

Average value of ratio of fractal dimension of the fragments of the class, this metric indicates the complexity of the shape. The index is an indicator of complexity that has a minimum value equal to 1, which represents a fragment to the shape of simple perimeter. Moreover, the index value 2, the greater the complexity of the shape marked by saliencies and re-entrances representing a complex geometry.

The mapping 1977 showed uniformity of content, with a mean of 1.33 (Figure 7 and Table 5). Considering values less than 1.33, was up 37.5% in urban patches with low complexity index, representing an absolute majority of 243 ha (85.55%) of the territory of urban District. Among the characteristics of these areas, had the effect of drawing the regular urban grid, making the relationship form the perimeter and area patches showed up straight.

Above average index, 3 urban areas had higher form complexity, covering only 1% of the total urban area. Are small patches with irregular morphology of the perimeter. See Figure 7 and Table 6.

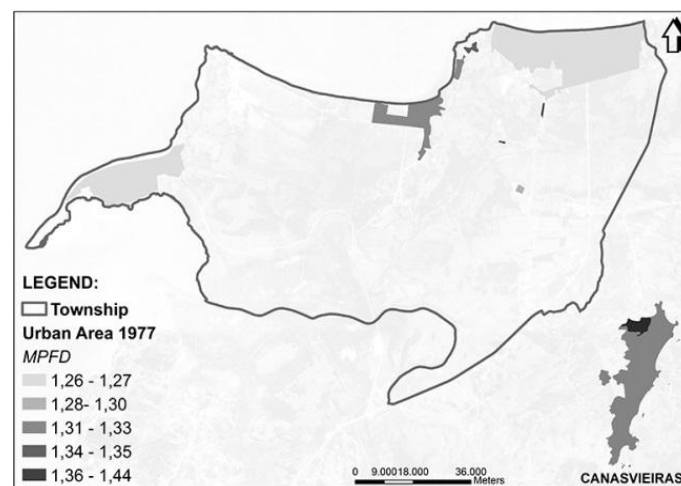

Figure 7. MPFD Urban area 1977 (source: Authors, 2014).

Table 6. MPFD Urban area 1977 (source: Authors, 2014).

Class	Patch	% cumulative	Area (ha)	% area
1,27	2	25,00%	242,18	85,13%
1,30	1	37,50%	1,20	0,42%
1,33	2	62,50%	38,28	13,45%
1,34	1	75,00%	1,93	0,68%
1,44	2	100,00%	0,90	0,32%

With the increased number of patches, as well as the total urban area from 1994, was the overcoming of average complexity index to 1.35 (Table 5 and Figure 8). However 43.48% of the patches had lower average behavior and covering 92% of urbanization. New areas were implemented, along the lines of gridded urban network.

In contrast, patches showed increasing of area and/or joint, getting forms/more jagged areas, reflected in a higher rate of complexity. Although part 13 patches, these total are only 7.7% of

the urban area of the cut (Table 7). Factors related to the growth of subdivisions of agricultural areas, linked to the period of extensive demand for urban land since 1970, which led to heterogeneity of urban mesh, with complex morphology reflected in the composition "fish spine".

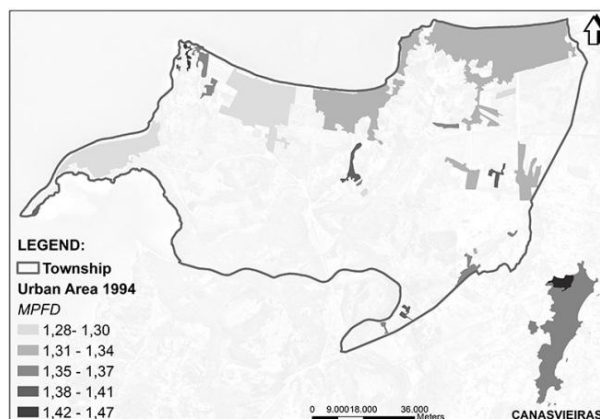

Figure 8. MPFD Urban area 1994 (source: Authors, 2014).

Table 7. MPFD Urban area 1994 (source: Authors, 2014).

Class	Patch	% cumulative	Area (ha)	% area
1,30	4	17,39%	171,83	31,67%
1,34	6	43,48%	328,92	60,62%
1,37	7	73,91%	24,68	4,55%
1,41	4	91,30%	14,22	2,62%
1,47	2	100,00%	2,90	0,53%

Mapping in 2013, there were proportionally to the increase of average complexity index of 1.39, the growing urban fragments, as well as its total area (Table 5 and Figure 9). Over 50% of the fragments were characterized by low complexity of form, related to the increase, as well as the emergence of new urban areas following the regular patterns. Compose accounted for 95.5% of the District (Table 8).

With the conurbation of urban patches, was a reduction of the complexity index thereof, which is clearly noted a urban growth marked by the fill of areas.

Among the areas with increase in complexity index, is one of the larger fragments. Unlike the behavior of other patches where there was the development of urban voids, it went through a urban expansion process of growth coupled with clustered branch. Aspects which contributed to a jagged fractal.

In general, the spatiotemporal analysis diagnosed increased areas accompanied by the appearance of smaller fragments. Thus, in the course of 40 years had as feature the largest display of these fragments relative to the context of its insertion, resulting in contact with other urban areas subsequently, through its fill or merger. It, resulted more symmetrical, coming of a regular pattern of urban mesh. Other fragments with higher rates reflected the development, often, the appearance of new and isolated areas, or with patterns of expansion inform of "branches", kind of arms, the morphology characteristic "fish spine".

Table 8. MPFD Urban area 2013 (source: Authors, 2014).

Class	Patch	% cumulative	Area	% area
1,33	8	25,00%	470,33	62,42%
1,37	9	53,13%	249,74	33,15%
1,41	10	84,38%	29,58	3,92%
1,49	4	96,88%	3,80	0,50%
2,00	1	100,00%	0,00	0,01%

NNDist- Nearest neighbourhood distance

Average value of the nearest neighbor of the fragments of the class, it was realized that in 1977 had 3 significant urban nuclei distributed in the territory. The urban patch with 164.10 ha, about 57.6% of the total, as well as 34.87 ha and 12.26% of the total urban area is characterized by having in his small fragments adjacent urban areas (Figure 10 and Table 9).

The third representative area, with 27.67% of the total (78.71 ha), proved to be the most isolated, with a distance of almost 3km.

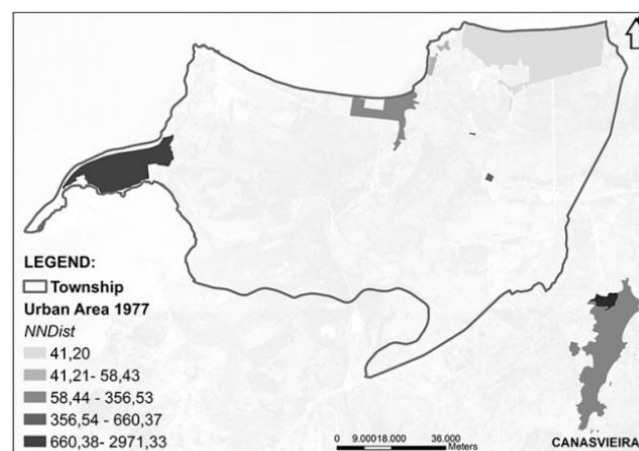

Figure 10. NNDist Urban area 1977 (source: Authors, 2014).

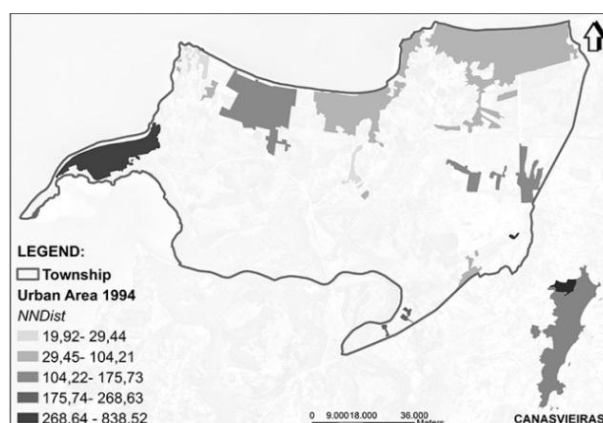

Table 9. NNDist Urban area 1977 (source: Authors, 2014).

Class	Patch	% cumulative	Area(ha)	% area
41,20	2	25,00%	164,10	57,68%
58,43	2	50,00%	5,34	1,88%
356,53	1	62,50%	34,87	12,26%
660,37	2	87,50%	1,47	0,52%
2971,33	1	100,00%	78,71	27,67%

Arising from urban growth, the period of 1994 was marked by a substantial reduction of the distance between urban areas (Figure 11). More than 60%, both in relation to the number of urban nuclei as the total urbanized area were virtually interconnected, since the distances were between 19 and just over 100m (Chart 10).

With the development of a significant new area of representative fragments, there was a substantial proximity, where the greatest distance was under 1 km.

In addition, sets of small areas incorporated, contributing to the reduction of distances.

**Figure 11. NNDist Urban area 1994 (source: Authors, 2014).****Table 10. NNDist Urban area 1994 (source: Authors, 2014).**

Class	Patch	% cumulative	Area(ha)	% area
29,44	4	17,39%	17,37	3,20%
104,21	11	65,22%	314,47	57,96%
175,73	4	82,61%	137,52	25,35%
268,63	2	91,30%	3,69	0,68%
838,52	2	100,00%	69,51	12,81%

Regarding the analysis of 2013, it is predicted that changes have occurred in relation to the differential in categories (Figure 11: NNDist Urban area 1994 and Figure 12).

In the first 4 classes there was an increase of distances, which reflected the processes of joining several fragments and deployment of new more distant urban nuclei throughout the territory (Figure 12).

Already the distance of fifth category remained stable (838.52 km), showing virtually no growth or emergence of new nuclei, demanding a territorial dynamic reduction on west sense of District (Table 11).

From this, analyzing the Table 5, it was realized that the process of urbanization, where there was substantial proximity to urban areas, occurred between 1977 and 1994. Compared to 2013 was maintained almost constant distance, and increased urban areas happened towards a consolidation of existing urban nuclei.

Table 11. NNDist urban area 2013(source: Authors, 2014).

Class	Table	% cumulative	Area	% area
49,38	13	40,63%	592,42	78,63%
114,01	11	75,00%	71,85	9,54%
226,28	4	87,50%	17,60	2,34%
444,81	3	96,87%	3,12	0,41%
838,52	1	100,00%	68,47	9,09%

Final discussion

Metrics, when treating about the size, shape, geographical position and typology provided the recognition and realization patterns changes caused by urban growth, allowing to measure the structures, better comprehension and greater accurate of the processes and interactions of city areas over 40 years in Canasvieiras District.

An urban dynamic characterized by rapid expansion, accompanied by the interests and pressures of the real estate and tourism market, which led to the construction of buildings along the land situated on the boardwalk, in order to attract more tourists and people seeking to possess a property on the waterfront. Especially where private capital was responsible for the parceling paper of smallholdings, which were fishermen and farmers, without any organ or policies of inspection.

Thus, the application of metrics in spatiotemporal analysis allowed us to identify and measure how much these processes in economic order, tourist, social and political reflected in the urban morphology of study area.

The elaboration of thematic cartography from the generated database of spatial metrics enabled confront the various stages of urban evolution, identifying the interactions between urban patches and the ways in which patterns and interactions have changed over time.

Thus, the use of spatial metrics in urban studies shows an instrument of evaluation and planning of space, indicating favorable and unfavorable situations, contributing to make strategic decision.

Abstract. *Kesennuma City, which is in northern part of the Miyagi Prefecture in Japan, was struck by the Tsunami in March 11th, 2011. The city has an area of 46 square kilometers, and that of 9.6 square kilometers, 20.5% of the area, were flooded. Reconstruction of city center, “Kesennuma Naiwan” area, which is the inner port area in Kesennuma Bay, was making little headway, since stakeholders have focused their arguments on the seawall construction. In fact, they should have more discussion about comprehensive reconstruction, including land-use plan, scenery and townscape, which would give the vibrancy around the waterfront. After two years after the earthquake, they established Community Conference organization comprising city planners and architects, and the recovery program has made by citizens, and progressing towards revival. There are two sources of the power of the resilience is in the urban form of Naiwan area. One is the dynamic urban form structured by townscape updated again and again taking in an advanced architectural design from overseas at every tsunami and conflagration. The other is static urban form, consisting of landscape, the sea and a mountain weave, climate, and scenery. The object of this research is to clarify the urban form that contributes to develop the resilient city, through the study on the contents and the process of making the recovery program of Naiwan area.*

Key Words: Tsunami; Resilience; Seawall; Scenery; Hazardous area

Introduction

The Naiwan, or Inner Port area is the old center of Kesennuma City. The area was marked by a beautiful fishing port, but most of the buildings have been swept away by the tsunami of 11th March, 2011, or their ruins were cleared away afterwards. (see the figure 1²³)

Since the Naiwan area, which encircles an inner bay, is itself closely surrounded by a mountain range that served as a near-by escape from the approaching tsunami, only few lives were lost during the tragedy²⁴. (see the figure 2 and 3)

In the aftermath of the disaster, the reconstruction authorities of Miyagi Prefecture designated a 4 meter-high seawall that would henceforth protect the formerly unprotected Naiwan area from future tsunamis²⁵. Realizing that a close relationship with the sea is the basis of their livelihoods and for community recovery, local residents launched a protest movement.

The local government of Kesennuma City supported the citizens in their effort to establish a Reconstruction Planning Council (hereafter ‘community council’) and to promote a joint, collaborative reconstruction process. However, most of the local residents were against the construction of any seawall. For the first two years after the tsunami, the council wasn’t able to

²³ Created by the author based on the materials ‘Regarding Tsunami Devastation of Major Areas,’ presented at the second Kesennuma City Disaster Reconstruction Conference, on 28th March 2012.

²⁴ Based on the materials ‘Damage Situation of our City after the Great Earthquake,’ presented at the first Kesennuma City Disaster Reconstruction Conference, on 28th March 2012.

²⁵ Based on the document ‘About setting the Heights of Seawalls along the Coast of Miyagi Prefecture’ that was presented in the Miyagi Coastal Local Coordination Meeting on 9th September 2011.

discuss about concrete reconstruction plans, such as revitalizing the local shopping streets or the reconstruction of residences.

In the Reconstruction Promoting Conference, set-up by Kesennuma City, the perception developed that the reconstruction planning had become delayed because of the lingering seawall problem²⁶. At this stage, the residents, who had been opposing the seawall plans of far began to give up and came to think that if the seawall is something that is absolutely necessary for the reconstruction to move on, they must accept it for good or worse.

The citizen leaders of the Reconstruction Planning Council, however, decided to propose a new plan in order to mitigate the impact of the next tsunami without being required to build the proposed, high seawall. They sought to reorganize the planning system, which would now closer reflect the opinions of the citizens²⁷. Institute of Urban and Regional Studies, Waseda University appointed as a specialized agency for the urban design.

As an adviser I have been supporting the Community Council in order to promote citizen-based planning. In this paper I want to discuss the process of reconstruction planning, which I relate to the specific urban form of the Naiwan area as well as to the process of making the recovery program, and I will show how that contributed to the development of a more resilient city.

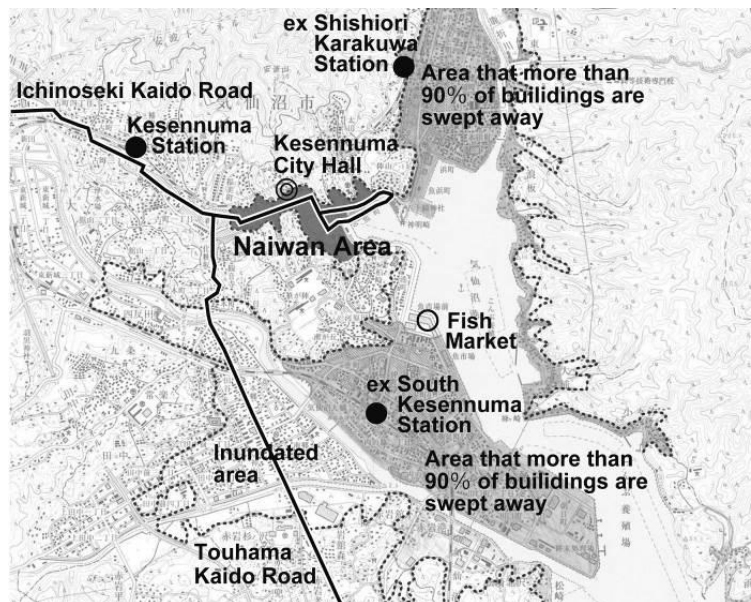

Figure 1. Devastation around Naiwan area by the tsunami of 3.11: Compared to the area around South Kesennuma and Shishiori-Karakuwa station that developed from wide wetlands and paddy fields in the Meiji Era, the tsunami damage was relatively light in the protected Inner Port area, that formed a safe city center and good natural harbor.

²⁶ Based on the materials 'Situation and Issues of the Restoration and Reconstruction Projects, p.10' of the fifth Kesennuma City Disaster Reconstruction Promotion Conference, on 28th March 2013.

²⁷ Based on Abe Toshihiko 'Seawall Problems and Citizen-led Community Development Issue in the Kesennuma Naiwan Area,' in: 'Town Planning Strong Resilience and Large Disaster Mitigation Task Force Report, Architectural Institute of Japan, p. 213-221, 2014.3.30.

Figure 2. Picture of Naiwan area after the tsunami 3.11, maintains the beautiful scenery: The Naiwan area surrounds a small bay and is itself wrapped by hills that rise between 20 to 40 meter above sea level. The mountains in the background are located at the opposite shore of Kesennuma Bay; 1.5km from the mouth of the Inner Port bay. The compact size of the bay with its 350 meter width in east-west direction and 250m width in north-south direction, has contributed to the formation of a coherent, human-scale cityscape that in turn facilitated lively commercial activities.

Figure 3. Harmonious streetscape of the sea and the mountains: Harmonious streetscape along the waterfront road with Mount Anba (left) and Jin'yama (right) in the background. The proximity to these two mountains allowed a quick evacuation of the residents before the tsunami arrived at the Inner Port area on 11th March 2011.

Beginning of the Seawall Issue

Along with other coastal areas in Kesennuma, Miyagi Prefecture decided to build a seawall that would withstand a so-called Level 1 tsunami – a tsunami that is likely to occur in intervals of a decade to 100 years. The municipality of Kesennuma City, on the other hand, has the responsibility for mitigating the impact of a more rare, so-called Level 2 tsunami – one that is comparable to the tsunami of 11th March 2011 and that is likely to happen every several hundred to 1000 years. The City is doing this by preparing evacuation plans and by designating the land that is likely to be flooded as Tsunami Hazard Area. Here residential functions are generally not to be permitted²⁸.

In autumn 2011, in the first recovery plans, a seawall with a height of 6.2 meters above sea level was designated by Miyagi prefecture. A tsunami defense with a height of 6.2 meters would only appear with a visible height of 4.4 meters, since the ground level of the Inner Port area would be raised by 1.8 meters. Since there was no seawall before the tsunami disaster, most people in the Naiwan area objected to these plans.

²⁸ Based on the Tsunami Regional Development Act, enacted 2011.12.14

Tsunami simulations that were carried out for recovery plans in other parts of Kesennuma Bay later led to a changed location of seawalls in the Naiwan area and a height reduction by 1 meter. Although the seawall would be now only 5.2 meters high, the feelings of locals did not change, because the sea was no longer visible from the port area.

For this reason, the deliberations between the Community Council and Miyagi Prefecture were making little headway. However, unless the location and the height of the seawall were not decided, the Tsunami Hazard Area could not be designated either. Furthermore, the placement of roads and parks could also not be decided if the inhabitable areas were not clearly outlined. Furthermore, if Land Readjustment procedures were not to be initiated soon central government subsidies for the reconstruction of residences and shops would expire. Based on the plans of Miyagi Prefecture, the sea and the town would be separated by a high seawall and thus it seemed uncertain if the fishery industry and the tourism sector could be revived in the Naiwan. Worse, neither residences nor stores could be rebuilt in this situation.

Turning point of the Seawall Issue

Two and a half years had passed since the tsunami, when the beginning of deliberations between the Community Council and the governor of Miyagi Prefecture marked a turning point. The governor suggested two possibilities: First, if a breakwater would be placed in the entrance of the bay, the height of the seawalls along the basin of the Inner Port could be lowered. The second option would be a setback of the seawall from the quay, and not to construct any seawalls between the bay and areas without residential functions, such as fishery or tourism facilities. Before these deliberations with the council, the governor had categorically ruled out any changes regarding the location and the height of the seawalls.²⁹

After the governor had shown his readiness to amend plans, the situation changed significantly. So far the people had been opposing the seawall plans, but now they began to change their minds: They realized that if they were to continue their opposition, the revival of the city would not progress and more and more people would turn their backs to the Naiwan area. The council decided therefore to resolve the seawall issue as soon as possible and it offered an own, comprehensive seawall plan to the Miyagi governor.

The core members of the Community Council formed a study group and examined how the prefectural planners had calculated the height of the seawall. They then demanded from the prefecture to re-simulate several alternative plans in which placement and heights of the seawall varied, in order to arrive at a design with the lowest possible visual impact. At first, they developed a proposal in which the seawall was further set back than in the original prefectural plan, and designed the waterfront area in a way that people could enjoy good views of the sea. They also proposed to construct a breakwater at the entrance of the bay, which would allow to lower the seawall height by 1 meter, because of the tsunami-obstructing effect³⁰. As a result of the simulations, they found that the height of the seawall could be reasonably lowered to 3.8 meters, which is 1.4 meters lower than the original height. (see the figure 4)

²⁹ Press conference on 24th December 2013, where the governor of Miyagi announced the possibility of changing the position and height of the seawall in the Inner Port area.

³⁰ See Miyagi Prefecture 'Development Guidelines for Tsunami Evacuation Facilities', p.73-6, March 2012.

Figure 4. Model of off-shore breakwater planned by the Community Council: Model of the Naiwan area with an off-shore breakwater at the mouth of the bay. Apart from studying possible obstructions to shipping, the Council also explored ways of utilising the breakwater as tourist attraction: Its visual appearance could be improved by greenery and an observatory at its tip would allow to spot incoming ships and ferries. The model has been build by the Urban and Regional Research Institute of Waseda University.

The Problem of the Tsunami Hazard Area

Another problem arose from the designation of the Tsunami Hazard Area: Based on a local ordinance of Kesennuma City, even if a place would be inundated by only 1 centimeter in the simulation of a Level 2 tsunami, it would need to be designated as hazardous area,³¹. In the case of rebuilding residences in an area with such designation, this meant that the foundation or the ground level of the house would need to be raised above the simulated inundation level. Also, the provision of welfare facilities in the first floors would not be allowed and the city would not provide any subsidies to people willing to rebuild their houses here. Thus, if the Tsunami Hazard Area expanded there it could mean that the number of people living in the Naiwan area could be greatly reduced.

The seawall height of 3.8 meters that the Community Council proposed achieved both, preserving the view of the sea and protecting the area from a Level 1 tsunami - likely to occur every few decades. However, with this height, the area that was only lightly damaged by the 2011 tsunami would have to be designated as a Tsunami Hazard Area, due to extensive, simulated flooding in the event of a Level 2 tsunami, with all the negative implications. (see the figure 5)

Figure 5. Level1 tsunami simulations for Naiwa area: Tsunami simulations for Naiwan area based on two alternative coastal protections, discussed in the Reconstruction Town Planning Council. A December 2013 simulation (left) showed that in the case of a 3.8 meter high seawall along the port basin, combined with an off-shore breakwater at the bay mouth, wide areas of the adjacent city center would be flooded. Another simulation of February 2014 (right) showed that without an off-shore breakwater and an assumed 5.1 meter high seawall, the level1 tsunami inundation would be significantly less. The inundated, yellow area of the right diagram corresponds to the Tsuanmi Hazard Area that the City designated.

³¹ The area designation has been proclaimed on 9th July 2013, based on the Kesennuma Municipal Ordinance for Disaster Risk Areas.

Settlement of the Seawall Issue

The mayor of Kesennuma City was concerned about the question whether the offshore breakwater could cause harm to the water quality of the inner bay and therefore opposed the idea. Without the breakwater, however, a seawall height of 5.1m would be required. To solve this problem, the Community Council requested to construct a 3.8 meter-high concrete base structure, with an additional 1 meter steel structure at the top that could move up automatically in the event of a tsunami approaching. Even though the costs for such a movable seawall would be comparatively high, the governor of Miyagi Prefecture accepted the proposal by the Community Council, since the Inner Port is the central area of Kesennuma City, and since it plays an important economical and symbolical role; worth to be protected from tsunamis.³²

If the ground level of the area, protected by the seawall would be raised by 1.8 meters, as originally planned, the 4.1 meter-high seawall structure would still appear 2.3 meters high and blocking views from the town to the sea. Thus, the Council proposed to raise the ground level of the protected area to 2.8 meters instead, so that the seawall would only appear 1.3 meters low. More than 3 years after the tsunami disaster, finally, the seawall issue in the Naiwan areas was settled. (see the figure 6)

Figure 6. Section of the seawall proposal in March 2013: Section of the seawall proposal that the Reconstruction Town Planning Council submitted to the municipal government of Kesennuma in March 2013. In order to ensure unobstructed views of the sea and still provide for a coastal protection with an overall height of 5.1 meters, the ground level of the urban area behind the seawall could be raised to 2.8 meters while a movable structure at the top of the dike would move up in the event of an approaching tsunami.

Dynamic Urban Form = Resilience

There are many towns and villages where the people are opposing plans of constructing excessively high seawalls, yet in most of these cases, the heights couldn't be reduced. Thus, the construction of seawalls is proceeding without agreement between the citizens and their local governments. Why was it possible to conclude an agreement in the case of the Naiwan area?³³

The most important factor is that although the seawall dispute had started with the debate of pros and cons and with an initial, fundamental opposition, at a later stage the discussion moved forward, beyond mere opposition; towards the issue of exploring what could be an ideal urban form, best able to cater to the lives of future generations in the Naiwan area.

³² Press conference on 14th January 2014, where the governor of Miyagi announced to consider the adoption of a movable seawall around the Inner Port area.

³³ On 14th May 2014 at the commemoration symposium for the 45th Anniversary of the Japan Federation of Bar Association Pollution Control and Environmental Protection Committee, with the title 'Disaster Reconstruction and Sustainability – Beginning to think from the Seawall Problem', a report was presented about the problem of consensus building from the perspective of local residents and experts.

Miyagi Prefecture's stance was originally that "in order to live in Naiwan, we need to construct a seawall to protect the life and property of all residents". Naiwan locals, however, opposed this view: "In order to live in Naiwan, we don't need to construct the seawall. We need to recover our relationship with the sea and preserve the beautiful scenery, in order to foster tourism and regenerate the fishing industry." Thus, before centering a reconstruction discussion on the pros and cons of a seawall, it would have been more helpful to discuss which new urban form would better serve a holistic recovery from the tsunami disaster.

While maintaining its close relationship to the sea and to the surrounding mountains, and while responding to the varied and profound environmental and social changes since the foundation of the city, the Naiwan area has been changing its urban form dynamically and thus it retained its role as the central area of Kesennuma. The members of the Community Council recognized this fact. (see the figure 7)

As an urban designer of Naiwan area, I promoted the design method making consideration of dynamic urban form. The members of the council have discussed about alternative recovery plans during numerous workshops, aided by the use of a 1:200 scale model that we proposed. (see the figure 8) They developed plans for a new urban form along the waterfront that perfectly blended the future townscape with the seawall with our support. (see the figure 9)

In the reconstruction planning process in central Kesennuma the following urban form-related characteristics must be pointed out:

First, it was feared that the citizen's valuation of the waterfront would be lost, if the the seawall were to block the views of the sea from the city. In other words, the concrete form of the embankment would significantly affect the nature of urban form in the Inner Port area. Since the citizens were keenly aware of this, the relationship between the port district and the sea played a central role in the discussions. At first, the mayor of Kesennuma City said that he cannot change the height and placement of the seawalls by changing the national standards. But the citizens' movement changed the mayor's mind. From now on, he will change them based on local peoples' opinion.³⁴

Second, since the land reclamation in Kesennuma port in the early Meiji Period until the 1950s, transformations of the urban form sought to strengthen the relationship between town and sea. However, between the 1960s and the 2011 disaster the new commercial center of gravity has moved away from the sea. In the current earthquake reconstruction plan, thus, great emphasis is put on recreating closer links between town and sea.

The most important point is the main facilities for the locals and tourists will be relocated to the waterfront area where the fish market has been located about sixty years ago.

Third, over time the roads in the Inner Port area have been repeatedly widened in order to adapt them to the needs of the age of motorisation. In order to tap into national reconstruction funds that are only available for a limited menu of narrowly defined reconstruction projects, the local government decided to carry out a land readjustment project in the Naiwan area. This would result in a further, unnecessary widening of roads. The council hotly debated the issue of how to improve these initial plans that could further impair the connections between city and sea. Without reference to the historical urban formation of the area, a central axis was proposed along which tourist attractions and commercial facilities would line up.

The above suggests that the urban form produces a close relationship between town and the sea in the Inner Port district, and it is manifest of a strong resilience.

³⁴ On 14th May 2014 at the commemoration symposium, there was a comment about the seawall by the mayor of Kesennuma City.

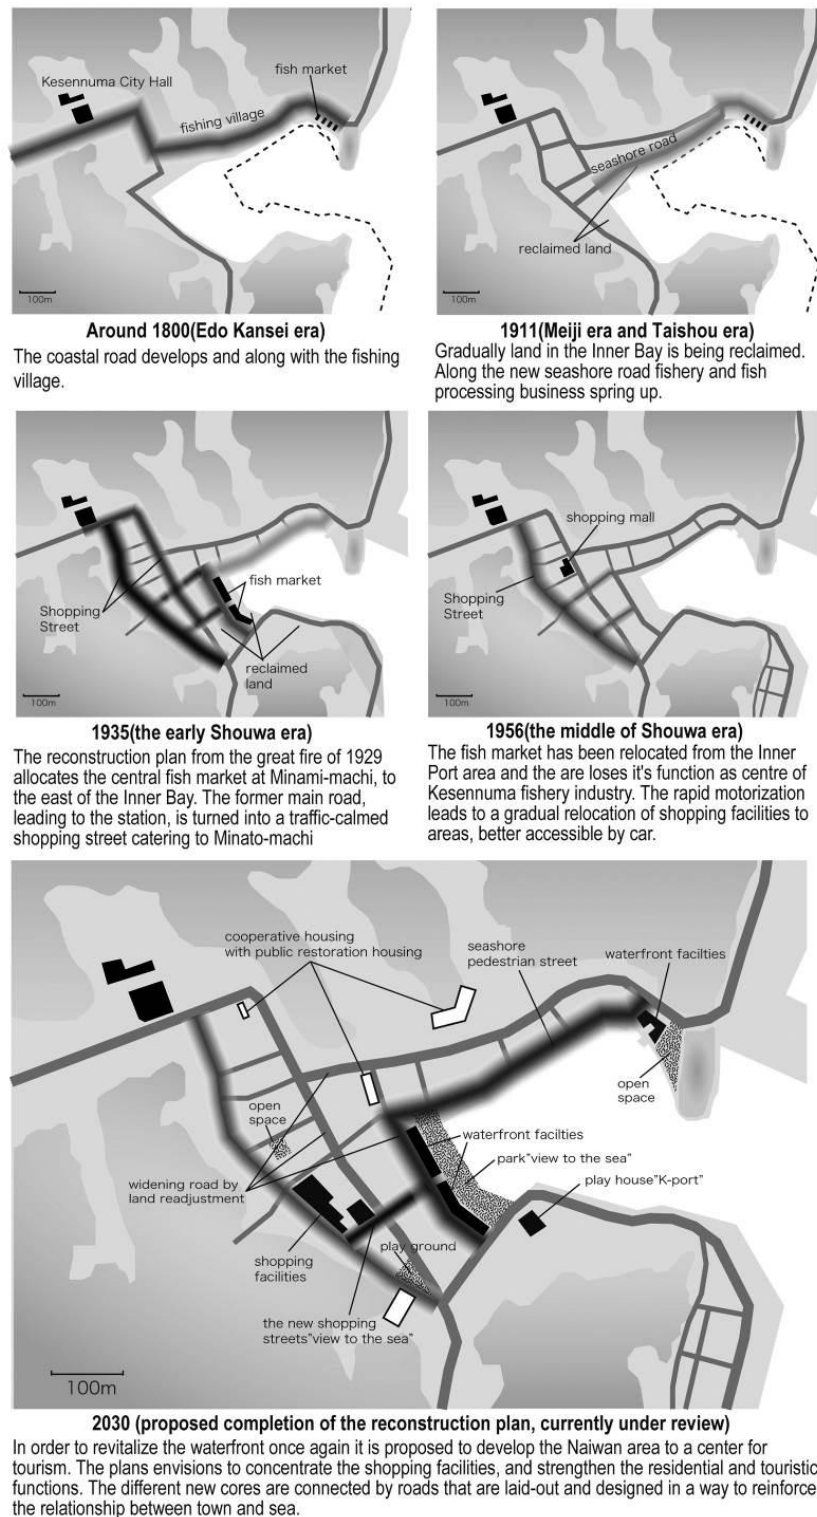

Figure 7. Dynamic Changes of the urban form by the historical development: Historical development of the Naiwan area and central Kesennuma, from the feudal Edo Era (1800), through the late Meiji Era (1911) and early Showa Era (1935) until 1956. These diagrams are based on the analysis of historical maps and photographs by the author. The 2030 diagram is based on the 'Inner Port Area Reconstruction Planning Statement'.

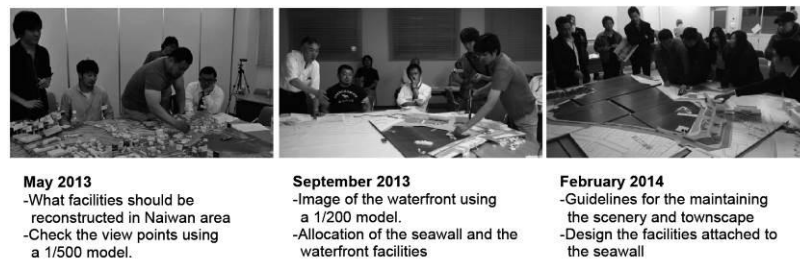

Figure 8. Design workshop process held in the Community Council: Between May 2013 and February 2014 the Naiwan Reconstruction Town Planning Council examined alternative seawall designs in a series of workshops. A 1/200 model helped to visualise the spatial implications of the different plans.

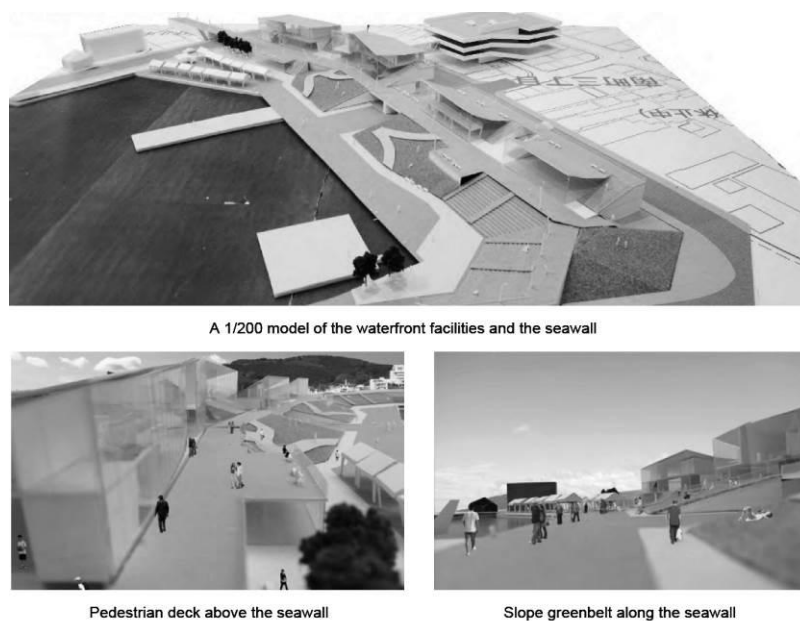

Figure 9. Future image of the waterfront in the Naiwan: Future image of the waterfront area and the seawall as shown in the 'Naiwan Area Reconstruction Planning Statement'. The model has been build by the Urban and Regional Research Institute of Waseda University.

Future Perspectives

We all recognized that we cannot build back the Naiwan area better than before the tsunami disaster; regenerate the fishing industry, tourism, town- and landscape design, as well as improving disaster preparedness by solely relying on the governments strictly earmarked reconstruction projects and funds.

But we also realized that it will be very difficult to implement such a proposal that seeks to harmoniously fuse the seawall with the townscape, and to regenerate a new urban form, only by utilizing public funds.

Now starting from a comprehensive future vision, we are currently examining which parts of the overall recovery project are most urgent, such as the underground drainage system; which parts are eligible to what kind of central government funding sources, and which parts can be

tackled later, after further careful discussion. Through such a strategic approach, they hope to implement the plan incrementally, with every element being part of a holistic strategy.

Many towns of the Tohoku area were already in economic decline before the disaster happened on 11th March 2011 and it is clear that the affected areas cannot recover without reconstruction funds from the national government. Usually, it is the central and local governments that take the initiative in reconstruction planning in a top-down manner, but the case of the Naiwan area in Kesennuma is different. We will surely find the regeneration of a new urban form here soon, which is fostered by the unique, dynamic urban structure that has proven its resilience over history, supported by the strengths of its citizens in the present. (see the figure 10)

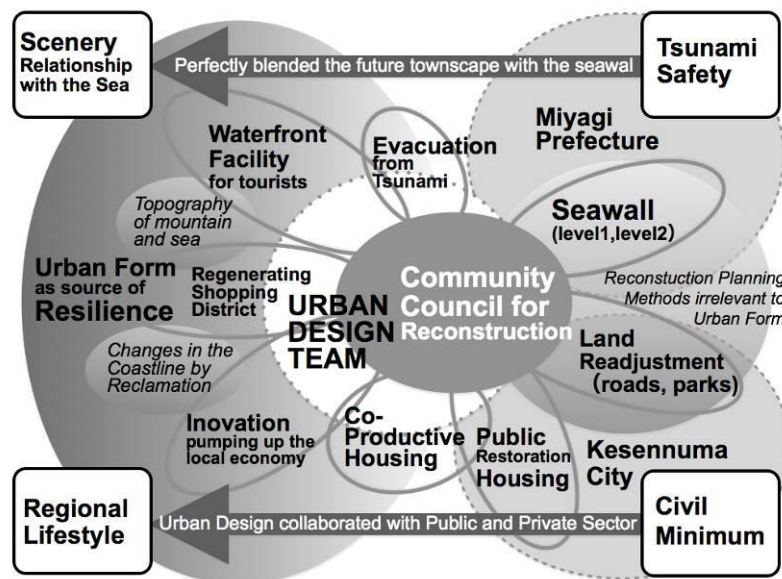

Figure10. Relationship between the urban form and resilience: The public sectors were promoting planning of the seawall and land adjustment for the tsunami safety and the civil minimum. But from April 2013, our urban design team is planning the reconstruction plan with the community council by discussing about the urban form considering the scenery and the regional life styles.

Abstract. *The quality of city's living environment spaces has an impact on all aspects of life. It is essential that the spaces we create and improve through the principles of sustainable urban planning will influence how we feel. For the fast expansion of globalization with the unplanned organization of an urban area has affected to develop a city's sustainability within the means of the environments, social and economic foundations. However, those inappropriate approaches of development strategies such as, city's geometric force of density, undefined land-use pattern, different transformation systems and build forms could tremendous change to our urban climatology. Air circulation as one of the most prominent urban principles of urban climate is an effective question for our local and global area where air circulation flows are discontinuing by different level of building form, its height, wrong orientation and building to building buffering spaces. Due to no contact with sunlight, some buildings are obtained cold temperature and during seasonal change it absorbs more cold temperature and increase running expenditure with discomfort living situation. On the other hand, sun orientated surfaces of the build forms are also absorb heat and urban area's temperature extensively space heater than its surrounding rural areas. In this paper we focus on urban build-form orientations, analysis those, its performance and how to reduce solar heat grain through the sustainable indicators of proper air flow circulations to develop an eco-city in the tropical area.*

Key Words: Air circulation, orientation, urban form, eco-city, built environment.

Introduction

Cities are extremely responsive to urban climate unsteadiness and inconstancy and capable to change their own climates (Srivani and Kazunori, 2011). Urban climate is a fundamental issue which not only affects regional and worldwide climates but also have an effect on urban liveability (Grimmond, *et al*, 2010; Huang, *et al*, 2008; Srivani and Kazunori, 2011). It can be modified and enhanced to fulfil the necessity of resident by urban planning ways. The quality of city's living environment spaces are depend on the principles of sustainable urban planning within the means of the environments, social and economic foundations (UDC-1, 2007; Brundtland, 1987; UNCED, 1992). For the fast expansion of globalization with the unplanned urban growth has affected to develop those kinds of city's sustainability.

It is estimated that over 50% (CIA, 2010) of the world's population now lives in cities and urban area. However, these inappropriate approaches of development strategies such as, city's geometric force of density, undefined land-use pattern, different transformation systems and build forms could tremendous change to our urban climatology (Oke, 1988). Furthermore, temperatures are extensively warmer than its neighbouring rural areas. This statement called an urban heat island (UHI) effect where have unprivileged outdoor air quality with weaken ventilation and, which promotes multiple sensitivity to upcoming global changes (Grimmond, *et al*, 2010). From the book of Koenigsberger, *et al*, (1973), where we have found that air temperature in an urban area can be 8 degC higher than in the surrounding rural area and a variation of 11 degC has been reported.

The paper has seven sections, including this introduction. Section 2 discusses on the relationship between urban form and urban climatology with relates eco-city development and

defines. Section 3 highlights few considerations of orientation on build-from pattern. Section 4 discusses the impacts of urban formation throughout air flow. Section 5 offers few conceptual urban formation patterns through sustainable indicators of proper air flow circulation. Section 6 offers a conceptual framework for assessing the air-oriented urban formation of the eco-city. Section 7 presents the paper's conclusions

Eco-city: urban form and urban climatology

Form is difficult to define. Generally, urban form is a combination of characteristics which related to land use patterns, transportation system, and urban design (Handy, 1996). Lynch (1981), defines urban form as "the spatial pattern of the large, inert, permanent physical objects in a city".

In urban design compendium (UDC-2), (2007), shows that urban buildings forms might be modelled for solar access or shade for shelter, exposure to winds depending. Urban form has a key influence on climate change, almost 30 per cent of carbon emissions come from building structures and a further 25 per cent from transport. To succeed in integrating renewable energies in established urban structure, the actual behaviour and the microclimate performance of the urban forms have to be precisely identified. Geometry is a changeable that may be controlled for the preservation of bioclimatic conditions, besides others functional, socioeconomic and symbolic parts of the urban form (Al-Qeeq, 2010).

The manifestation of "sustainable development" as a popular concept (Jabareen, 2004) has revived discussion about the form of cities. To achieve sustainability, this challenge has motivated and encouraged scholars, architects, planners, local and international NGOs, civil societies, and governments to search for new frameworks of urban form by the study of various parameters of urban climate modelling and integrate them into planning and design efforts (Nyuk, *et al*, 2011). Moreover, there is no universal concept that allows us to evaluate these approaches, planning schemes, and common policies (Jabareen, 2006). Therefore the incorporation of basic knowledge of urban climatology in the urban planning procedure has become more vital. From Jabareen, (2006), The Eco-city concept has a new definition for sustainable development in urbanization.

The Eco-city

An eco-city is an ecologically healthy city, designed with consideration of ecological impact, inhabited by people dedicated to minimization of required inputs of energy, water and food, and waste output of heat, air pollution - CO₂, methane, and water pollution (Register, 1987; Novotny, *et al*, 2010). Greening and passive solar designs are the unique concepts of the eco-city. There are others that highlight the perceptions of greening and passive energy design, among them the Environmental City, Green City, Sustainable City (Girardet, 1999; Nijkamp and Perrels, 1994; Gibbs, Longhurst and Braithwaite, 1998), Eco-City (Roseland, 1997; Engwicht, 1992), Ecological City (OECD, 1995), Sustainable Urban Living (Girardet, 1992).

Basis of orientation on urban form

The unique concepts of building form orientation are might be respect its context and climate with few different point of views, like as, (1) optimize sun orientation reduce solar heat gain (Givoni, 1969; Koenigsberger, *et al*, 1973; Prasad, 2014), (2) air flow direction (Givoni, 1994; Koenigsberger, *et al*, 1973; UDC-1, 2007; Prasad, 2014) (3) site geometry (Simonds, 1961; UDC-1, 2007) (4) street layout (Shishegar, 2013; UDC-1, 2007; Bentley, *et al*, 1985; CABE, 2000) (5) Scenic view/vistas (Simonds, 1961; UDC-1, 2007) (6) Legibility layout (UDC-1, 2007; Bentley *et al*, 1985).

In the tropical climate, Building orientation is a major design consideration, mainly with consider to solar radiation and wind (Al-Tamimi, *et al*, 2011, Prasad, 2014). Whereas every morning and evening, sun directly radiate on east and west facade of build form, while north façade faces sun radiation throughout May, June July and August, and south façade faces it throughout November, December, January and February. Therefore in tropical area, building orientation mainly should be seriously considered not only with solar radiation but wind direction also (Al-Tamimi *et al*, 2011; Bentley *et al*, 1985). Givoni, (1994), also reported that the building orientation may be affected by the provision of efficient cross ventilation under the local wind direction which is key factor in tropical areas.

Impacts of urban forming on air flow circulation

Air flow circulation as one of the most important urban principles of urban climate is a valuable issue for our local and global region. For the different level of building form, its height, wrong orientation and building to building buffering spaces, air circulation does not flows frequently and uninterruptedly (Al-Qeeq, 2010).

It has been proved that the urban layout, the geometry and orientation of the street canyon affect the climate of the outdoor and indoor environments, solar access inside and outside the buildings, the permeability to airflow for urban ventilation, as well as the potential for cooling of the whole urban system (Ali-Toudert and Mayer, 2006). The urban layout influences the climate of the neighbourhood and that can even adjust it to improve the thermal comfort situations both outside and inside build form (Al-Qeeq, 2010; Al-Sallal and Al-Rais, 2012). It seems noticeable that street geometry as an urban design tool is more important in improving urban climate which allow to welcoming air flow than other factors of urban environments (Johansson, 2006; Shishegar, 2013).

Usually in towns, when winds face the number and range of obstacles they are flowed moderately (Al-Qeeq, 2010; Jabareen, 2006; Shishegar, 2013). However, some forms of urban structures such as long straight avenues or multi-storey buildings can source for significant air movement. As the air is brought down from high levels, high buildings increasing above low-rise building can generate strong turbulent wind conditions on the ground (Priyadarsini and Wong, 2005; Chan, *et al*, 2001; Al-Qeeq, 2010; Koenigsberger, *et al*, 1973).

Compactness is the method of minimising the amount of building facade exposed to the direct radiation of the sun. Therefore, the compact city consumes a small amount of air circulation for cooling building inner wall or outer façade (Jabareen, 2006; Al-Qeeq, 2010). Improperly selected and sited vegetation can change wind flow direction and provide discomfort living environment for both buildings and people (Al-Qeeq, 2010; UDG, 2006; Al-Tamimi, *et al*, 2011; Bentley, *et al*, 1985; UDC-1 & 2, 2007).

Sustainable indicators and applications for air oriented urban form

Climate responsive arrangement of buildings is important for the comfort and energy saving implications for its users; furthermore, it helps to preserve valuable resources in our planet (Roche and Liggett, 2001). Givoni, (1994), reported that Air movements inside a building depend not only on external wind velocity, but also largely on the architectural parameters. There are generally three techniques that are the use of shadow and air breeze, water elements, and the minimization of the impact of solar radiation which promoting the liability and comfort of human settlements (Al-Qeeq, 2010).

The sustainable indicators would not only be implemented all at once, but also faced difficult to uniformly implement throughout the city. New development areas should be designed to follow the guidelines, but old, built-up areas should be considered to improvement when opportunities arise from urban revitalization (UDG, 2006). Maximising the amount of space to

be naturally ventilated is one of the fundamental strategies towards reducing energy. The first step in minimising solar heat gains is to optimise the orientation and massing of a project specific to its location. Therefore, Establishing and understanding prevailing wind directions and how they work on specific urban area throughout the year will affect massing and orientation decisions.

Key indicators

To good natural ventilation of an urban area depends on the macro-environment. From Urban Design Compendium 1 & 2, (2007); Jabareen, (2006); Givoni, (1969, 1994); Koenigsberger, *et al.*, (1973); Prasad, (2014); Simonds, (1961); UDG, (2006) and Al-Qeeq, (2010), we have discovered various sustainable indicators and review again to implement those in tropical urban area with How to develop the Eco-city.

- site geometry for urban formation: to avoid elongated and linear site geometry which could possible outcome in single-aspect and wall effect, urban site should be separated for conducive to wind movements (Figure 1);

Figure 1. Site Geometry to allow more air flow.

- breezeways/air paths: to enhanced urban air ventilation in tropical dense area, breezeways should be created in forms of major open ways interconnected with major roads, inter-linked open spaces, amenity areas, building setbacks space and low-rise building corridors, through the high-density and tall urban form. They should be connected with mainly the prevailing wind direction routes, and as far as possible, to also preserve and funnel other natural air flows;

- street orientation, pattern and widening: an arrangement of main streets should be allied in parallel, or up to 30 degrees to the prevailing wind path, in order to take advantage of the penetration of prevailing wind through an urban area (Figure 2);

Figure 2. Orientation of street grids.

- the length of street gridiron at right angles to the prevailing wind direction should be as shorter as possible with a view to minimizing sluggish zones while maximizing breezeways across the urban area (Figure 3);

Figure 3. Pattern of street grids.

- to progress the air ventilation in the urban areas, the extending of streets along the prevailing wind direction is considered of high efficiency. (Figure 4);

Figure 4. Street widening/building setback.

- waterfront sites: waterfront sites are the gateways of sea breezes and land breezes due to the sea cooling and sun warming effects. To avoid blockage of sea breezes and prevailing winds, particular concerns should be given beside the waterfront like as appropriate scale, height and decentralised within high-density neighbourhoods (Figure 5);

Figure 5. Waterfront buildings should avoid wind blockage.

- height profile and form: a changing height profile with strategic nature of low-rise and tall build forms in the dense urban environment can help to prompt wind flow throughout the city; In generally, gradation of building heights an urban area would help wind deflection and avoid air stagnation to promote air movements. (Figure 6);

Figure 6. Varying height profile to promote air movements.

- congestion of high buildings forming a lofty wall-like arrangement should be avoided to the front of the prevailing wind or along the waterfront;
- tall buildings in a neighbourhood should be arranged in such a way as favourably block the wind;
- Stepping building height conception can assist optimise the wind capturing potential of development itself (Figure 7);

Figure 7. Stepping height profile to divert winds to lower levels.

- built forms that would generate a small eddy area to allow a highest of cooling air to flow around and throughout the build forms should be considered in tropical area (Figure 8);

Figure 8. Creating eddies that also result in building heat loss.

- stagger buildings;
- the arrangement of the building blocks should be staggered such that the build forms behind are able to receive the wind penetrating throughout the gaps between the build forms in the front line (Figure 9);

Figure 9. Staggered arrangement of build forms with sufficient spacing between forms.

- the adequately wide gaps should be provided between building blocks for enhancing air permeability and that should be at a face perpendicular to the prevailing wind (Figure 10);

Figure 10. Gaps between building blocks to enhance air permeability.

- podium structure;
- to enhance air quality of the pedestrian environment and improving comfort on street levels and impeding air movement, compact integrated development and podium structures with full or huge ground covered area on wide sites should be avoided where practicable. The following measures should be applied at the street level in the existing urban areas: providing setback parallel toward the prevailing wind; selecting non-building areas for part of large land parcels; creating voids in building facades facing wind path; reducing site coverage area of the podium to allow more open space at grade (Figure 11);

Figure 11. Reducing site coverage area of the podium to allow more open space at grade.

- where suitable, a terraced podium design should be adopted to direct downward airflow to the pedestrian level (Figure 12);

Figure 12. Terraced podium design.

- downwash wind;
- to reach the street level and to ventilate streets and allow air movement into buildings, Building design should consider capturing the downwash wind (figure 13);

Figure 13. Building geometry and layout to allow downwash wind.

- where appropriate, towers should adjoin the podium edge that faces the main pedestrian area or street perpendicular to the wind direction so as to enable most of the downwash wind to reach the street level (Figure 14);

Figure 14. Towers placed to enable downwash wind to reach street level.

- building permeability;
- the provision for higher permeability of building masses can be achieved by creating gaps between building blocks, between the podium and the building blocks built atop (i.e. a void podium deck) and within building blocks at various levels (Figure 15);

Figure 15. Gaps between the podium and building blocks to enhance air permeability.

- buildings should be as permeable as possible to channel airflow to the blocks in the back row (Figure 16). Sky gardens and double volume void decks can increase the permeability of blocks;

Figure 16. Sky gardens and void decks increase permeability of block.

Assessment of air-oriented urban formation to the Eco-city

Jabareen (2006) provided a thematic typology of literature from the sustainable development and environmental planning fields and recommended that urban sustainable development has conventionally been addressed at different spatial stages. He suggested the possibility of comparing the performance of typical sustainable forms on the basis of design concept criteria related with urban sustainability (see below Table 1).

Table 1. Sustainable urban form matrix: assessing the sustainability of urban form

<i>Design Concepts (Criteria)</i>	<i>Neotraditional Development</i>	<i>Compact City</i>	<i>Urban Containment</i>	<i>Eco-City</i>
Density	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High
Diversity	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High
Mixed land use	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High
Compactness	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High
Sustainable transportation	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High
Passive solar design	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High
Greening— Ecological design	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High
Total score	15 points	17 points	12 points	16 points

Note: Scores of the urban forms are highlighted in bold.

Source: Jabareen (2006).

The sustainable urban form matrix in Table 1 provides an assessment of the sustainability of the different urban forms. Significantly, this is a tentative consideration that is based on the literature review of the forms and not on experiential findings or field work (Jabareen, 2006). As shown in Table 1, the scores of the urban forms are highlighted in bold in each cell of the matrix (1, 2 or 3), and the final score for each form is the sum of these scores that is presented at the bottom. The results of the assessment, in Table 1, show that the compact city received the highest score followed by the eco-city and then by the neotraditional development, after that the urban containment received the lowest score (Jabareen, 2006).

It is clear from Jabareen's table, for example, that possible conflicts exist between compactness and passive solar design, because the higher densities linked with compactness would increase shading, in that way reducing solar access and no presence of air flow design. There would also be exchanges between compactness and ecological design, with higher densities impinging on green space aspects.

For the purposes of summary and analysis, we could well add a new row with same columns where indicate by previous three points (see below table 2).

From New matrix of Urban Form, the Grand Total scores for each form is the sum of with those previous scores that is presented at the bottom. The results of the assessment, in Table 2, show that the eco-city has received the highest score than both of the compact city and the neotraditional development. The urban containment received the lowest score here also.

Table 2. Sustainable urban form matrix: assessing the sustainability of urban form with additional criteria

<i>Design Concepts (Criteria)</i>	<i>Neotraditional Development</i>	<i>Compact City</i>	<i>Urban Containment</i>	<i>Eco-City</i>
Air oriented form design	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High	1. Low 2. Moderate 3. High
Grand Total score (Summation with previous total points of Table 1)	18 points	18 points	14 points	19 points

Note: Scores of the urban forms are highlighted in bold.

Conclusion

In practical situation of, many local authorities, governments, architects, planning consultants, landscape architects, and so on are grappling much further specifically with aspects of sustainable urban form through a variety of planning and design approaches and policies. The question is which urban form is the most sustainable and environmentally sound for the tropical urban area?

This study identifies the ideal indication of urban formation in the tropical area. To create an Eco-city with sustainable built environment in the tropical urban area, due considerations should be given to urban design concepts and ideologies in the planning and development procedure. Our tropical urban area therefore basically needs more breezy air flows for thermal relief and comfort in the built environment. To improved and long-term development of the wind environment in our city, it is so important to optimise urban design for more wind penetration, particularly to the public realm that urban form would be faced to air oriented.

According to the sustainable urban form matrix and key indicators of sustainable air flow circulation, this study concludes that air oriented urban form contributes to develop an Eco-city in the tropical urban area, where the Eco-city has accumulated urban greening, sustainable transportation system and passive solar design with highly concern of build form orientation to allow maximum air flow.

Territorial and urban form regulation: from Garden-City to Low Carbon City

Joana Mourão

Instituto Universitário de Lisboa, DINÂMIA'CET-IUL, Av. das Forças Armadas 1649-026 Lisboa, Portugal. E-mail: jfmno@iscte.pt

Abstract. *The control of atmospheric emissions is a question of urban planning at least since the end of the XIX century, when the industrial revolution started to disturb the urban environment (Tarr, 2002). "Our Common Future" (WCED, 1987) challenges brought this environmental concern back to urban research demanding for ecological urban form regulation methods, in particular to control the increase of energy demand and Greenhouse Gases emissions (Nijkamp, 1999). Analysing the concepts of Smokeless Cities and of Low Carbon Cities this article investigates the ecological purposes of territorial and urban form regulation methods, in two different moments: First, it analyses Smokeless Garden-City, proposed by Ebenezer Howard in the aim of social economy (Howard, 1949); secondly, it analyses Low Carbon City following "Our Common Future" (WCED, 1987) and "Prosperity without growth" (Jackson, 2009) using academic research in the aim of market economy (Cuchí, 2009; Mourão, 2012). The comparison of these two concepts shows that Smokeless Garden Cities and Low Carbon Cities depend not only on urban form but also on territorial form. Furthermore, it shows that, while territorial and urban form was possible to regulate by social economy zoning; on the globalized market economy such regulation requires accounting and integrating environmental costs on urbanism.*

Key Words: *Territorial Form, Urban Form; Garden City, Low Carbon Cities, Ecological Economics.*

Introduction

Several authors wrote about Ebenezer Howard's *Garden-City* (1898) and ecological urbanization, looking back more than one hundred years ago, on a perspective either of valuating this urban project or of criticizing it. If some found on this proposal a powerful territorial project to control urban growth (Hall, 1998; Peña, 1998), other saw (in particular due to the asylums segregated from urban areas) an eugenic utopia, even comparable to the Third Reich (Voigt, 1989). However, references to *Garden-City* as a model to which is worth to return are more common than the opposite ones.

Furthermore, *Garden-City* contents relating ecological purposes of planning, raised later on by authors as Ian McHarg (1971), are of particular interest for the discussion on methods for controlling environmental impacts of urban growth, as for challenges of "Our Common Future" ideology (WCED, 1987) and Climate Change (Stern, 2007). On another hand, this proposal contributed for the generalization of zoning procedures in urban planning, widely questioned by more recent planners (Mancuso, 1980).

Among urbanization environmental impacts, consumption of non renewable energy and resulting Greenhouse Gases emissions (e.g. Carbon Dioxide), are impacts which regulation is of particular relevance, since it can mitigate a global ecological risk (the rupture of the carbon cycle and global warming, among other crossed effects) and it can contribute to achieve prosperity *decoupled* from fossil fuels consumption (Jackson, 2009). However, to reduce this impact through urbanism practice, in particular in Southern Europe, has still not produced visible effects, probably due to the complexity of the globalized market economy and the weakness of local power. Looking backwards on time can bring us some inspiration for the research on this problem.

Smokeless city, an ecological purpose of urban form regulation at social economy

Ebenezer Howard's *Garden-City* proposal appears at the context of the agriculture crisis which affected England at the end of the XIX century (Hall, 1998). In face of this crisis Howard wanted to organize spatially the new industrial life, while countering the declining rural life. *Garden-City* proposal aimed, in first place, to return people to the country and rural life, and secondly, to conciliate social, industrial and rural development, at short and long term. Thus, it aimed not only to solve the urban problem of then, but also the agrarian problem, responding to the intents of several agrarian reformers of the time, which were concerned with the intense rural exodus in Europe (Peña, 1998).

"To-morrow, a peaceful path for social reform", first published on 1898 by the author, stands on a model of redistribution of population, employment and wealth, all trough the territory: *"there is a broad path open, through a creation of new forms, to a new industrial system in which (...) the distribution of the wealth will take place on a more equitable basis"* (Howard, 1949: 130). Thus, the will of integrating urban and rural life through territorial and urban form regulation, stands at the basis of *Garden-City*, together with the idea that the country could be so attractive as the city, and that these two realities could work as one: *"neither the town magnet nor the country magnet represents the full plan and purpose of nature. (...) town and country must be married, and out of this joyous union will spring a new hope, a new life, a new civilization"* (Idem: 48).

However, the urban revolution was showing the opposite tendency, and all over Europe people were leaving the country life in search of a better life and opportunities, flowing into the cities, congesting and contaminating the urban environment and rising the price of land, confirming Howards' assumption: *"perhaps no difference between town and country is more noticeable than the difference in the rent charges for the use of the soil (...) this enormous difference of rental value is of course almost entirely due to the presence in the one case and the absence in the other of a large population"* (Howard, 1949: 58-59). Population pressure over cities was causing several social and environmental problems and unqualified urban form development, specially visible on suburbanization, that Howard considered a way to the elimination of citizenship and solidarity (Peña, 1998).

Howard proposal of social reform was also directed to two main environmental problems of the industrial city: spatial congestion (urban form densification and degradation, i.e. *slums*) and environmental contamination (concentration of atmospheric pollution, i.e. *smoke*). To eliminate such problems rooted on the industrial city, he proposes a polycentric conurbation served by railways and water channels, where the non-built space is dedicated to agriculture and forest, while the built space remains contained in each urban settlement, ruled by rather high urban densities for that times: the central city has 58000 inhabitants on 12000 acres and satellite cities have 32000 inhabitants in 9000 acres (Figure 1). In average, *Garden-City* globally would have a density of around 900 inhabitants/km², a near value from the density of the metropolitan area of Lisbon in 2001 (850 inhabitants/km²).

Howard envisioned a dense urban form with few open spaces in its interior areas, compensated by the green belt of open spaces surrounding and filling the interior of the polycentric urban system: *"this principle of always preserving a belt of country around our cities would be ever kept on mind till, in course of time, we should have a cluster of cities"* (Howard, 1949: 142).

Figure 1. *Garden-City* represented as a *Group of Slumless and Smokeless Cities* (Source: Author, 2014, adapted from Howard, 1998).

The symbiosis between country and city is based on a spatial distribution of population, and on general principles about urban and territorial form: densities were ruling urban form (although the options of the built form were not defined) while the spatial balance between built space and open space was regulating territorial form (Figure 1).

This model would be only feasible with cooperative land ownership, being this cooperative responsible by the process of territorial and urban form regulation, while assuring that the *Garden-City* surplus would be used to the benefit of the cities infrastructures. Land cooperative ownership concept beneath such spatial model is discussed on the literature about social cities (Peña, 1998; F. J. Osborn in Howard, 1949; Hall, 1998), however territorial and urban form regulation method beneath *Garden-City* and its several ecological purposes are not so frequently approached. Indeed, the balance between built and open space, favourable to the built space at the urban scale (of the city) and favourable to the open space at the territorial scale (of the group of cities), was the base of *Garden-City* urban and territorial form regulation.

Howard proposal would, in theory, mitigate urban congestion and slums degradation through population distribution and regulation of settlement density, together with the safeguard of the structure of open and green spaces. These measures would also reduce environmental contamination problems, as smoke or waste, since that the right distribution of the urban form and its economical functions would minimize the conflict among different activities. Such environmental problems would be also mitigated by green space and by the location of industries, near the channels and railways, as also by the efficient non-polluting transport of people: “on the outer ring of the town are factories, warehouses, markets, coal yards, timber yards, etc., all fronting on the circle railway, which encompass the whole town, and which has sidings connecting it with a main line of railway which passes through the estate. This arrangement enables goods to be loaded direct into trucks (...) and so sent by railway to distant markets” (Howard, 1949: 55).

Territorial and urban form would follow the functions purposed, and therefore “urban form” expression does not appear on Howard text, while it is seen as a consequence of the town-country model. *Garden Cities* urban form, at the city scale, could be variable in each settlement

of the model, ever since accomplishing the rules of density and open space. Such variations are visible in figure 1, where each satellite city presents different urban forms.

Thus, the territorial and urban form regulation method of *Garden-City* derived from land use planning, managing territory and land as a “collective resource” and expecting that decisions on urban form, taken by the cooperative administration, would give priority to public interests, safeguarding the collective resources as non polluted soil, air and water.

Garden-City included ecological purposes addressing air pollution, but also addressing waste. Waste would be returned to the productive soil, near urban land, in order to fertilize it, to recover nutrients and to assure urban health: “*the combination of town and country in not only healthful, but economic (...) the waste products of the town could, and this without heavy charges for railway transport or other expensive agencies, be readily brought back to the soil, thus increasingly fertility.*” (Howard, 1949: 61-62)

Garden-City addressed also the energy problem: it would be supplied by electricity produced outside from the urban settlements and smoke, as waste, would be removed - or delocalized - from the urban environment: “*the smoke fiend is kept well within bounds in Garden City; for all machinery is driven by electric energy, with the result that the cost of electricity for lighting and other purposes is greatly reduced. (...) the refuse of the town is utilized on the agricultural portions of the estate*” (Idem: 55). Thus, in theory, smoke and waste would dissipate while bringing the country into the city.

In *Garden-City* the role of the free interstitial spaces between the satellite cities and the central city was larger than the one of a classic “*green belt*” around the city centre with hygienic purposes. These spaces were agricultural and ecological production units, crossed by railways and water channels, that would supply urban centres and would safeguard self-sufficiency by providing food, materials, fuels and ecological services (clean air, clean water). Therefore, urban growth would occur in proportion to the load capacity of the *hinterland* which was part of *Garden-City*. And, thus, urban *ecological footprint* would be compensated by land and ecosystem services performed at the multifunctional green belt of open spaces.

The reality of *slum and smoke full* industrial cities of then was even seen as reversible by Howard (Howard, 1949: 117). While Paris, Berlin, Glasgow or Vienna suffered radical interventions to clean the city with the opening of boulevards, green rings and the demolition of unhealthy slums, Howard argued that to develop *Garden Cities* would solve the problem of congestion and unhealthy environments, not only within the new cities, but also in London, while delocalizing inhabitants and relieving its pressure over the capital. However, the experiences of implementation of the model showed that, instead of relieving London it from social and environmental pressures, *Garden Cities* became green suburbs (Peña, 1998; Hall, 1998) with high mobility costs, hidden by the success of the new fascinating automobiles at the emergent *Fordist* times.

The role of ecological ideology on urban planning then and now

Howard achieved in the early XX century to propose a new ideology about land owning and land use planning with ecological purposes, in particular on what concerns to atmospheric emissions (smoke). However, today, more than one century after *Garden-City* proposal being first published, non polluted air in cities got much scarcer, and *Ecological Cities* are, on the globalized condition of nowadays, harder to idealize and concretize.

The role of ecological balance, renewal of air and water, which Howard attributed to the belt of agricultural and ecological open spaces today is not assured. To promote such open spaces ecological functions demands a high social control against illegal urbanization and environmental contamination, with high costs at a global scale.

On another hand, the ecological performance of such open spaces, in particular on what concerns to agriculture, is not always beneficial in several parts of the Globe, while economical

activity develops with very few ecological constraints, disrespecting the load capacity of the regions.

Howard's work shows that ecological purposes of land use planning are an ideological question, since the territorial and urban form regulation method of *Garden-City* was only feasible in the context of cooperative land management.

In the XX century ideology on ecology and sustainability was widely spread by "*Our Common Future*" report (WCED, 1987) and its inherent concept of sustainable development. Through this report, some of Howard aims became recognized at global scale in the end of the XX century, and on its sequence others, as climate change, were added (Stern, 2007). However, ecological ideology is still rarely transferred to land use planning and urbanism theory, on the contrary of what occurred with *Garden Cities* during the *Pre-Fordism* times.

Indeed, a planning method relating territorial form to ecological performance of cities facing automobiles, only appeared more than 50 years after, on the work of Ian McHarg (1971). Such research is still in course, leading us to a recent proposal on ecological urbanism, with variable meanings all over the world, known as *Low Carbon Cities* or also as *Low Carbon Urban Metabolism*.

Low Carbon Cities, a path to restrict urban energy demand at market economy

Recent research on urbanism identifies the study of the energy-carbon flow (among other flows of the social metabolism) as a relevant field of research to achieve a more ecological territorial and urban form, mitigating climate change since Carbon Dioxide is the principal Greenhouse Gas (Stern, 2007; Camagni, 2002; Newmann, 2006). *Low Carbon Cities* are understood as urban systems which demand few fossil fuels and produce few carbon emissions. However, *Low Carbon Cities*, as all contemporary cities, depend on globalized markets and, therefore, require an integration in a *Low Carbon World*.

The same has happened with *Garden Cities*: its reproduction and generalization would also had demand a *Garden-World*, where densities and open belts would be respected on the long term, all over the world. Thus, the real challenge of *Low Carbon Cities* is the one of a *Low Carbon Economy*, and such challenge requires a strong global ideological endorsement. "*Our Common Future*" report could had been the motor of such ideological endorsement, as *Ecological Economics*, which arose during the 70's of the XX century and inspired planners and an ecological planning method called "*Design with nature*" (McHarg, 1971).

Under *Ecological Economics* the limitation of entropy, and the consideration of environmental costs on the evaluation of urban development scenarios, became key purposes for a more ecological economy. *Low Carbon Cities* give shape to such purposes, conceiving spatial scenarios of low fossil fuels consumption, envisioning an expected future either of scarcity or of full internalization of environmental and climate change costs. But while such future is not recognized as reality, few *Low Carbon Cities* turn reality.

Also only two *Garden Cities* were created in reality, while its model inspired land use planning and urban form theory and practice all over the Occident. The same seems to occur with the concept of *Low Carbon Cities*: It caused a considerable amount of academic studies and innovative proposals, conflicting with urban and land use planning dominant practices and worldwide urbanization trends, so far inspiring several students and academics.

Furthermore, although few *Low Carbon Cities* still exist in reality, territorial and urban administrations all over Europe are committed with the low carbon goal (*Covenant of Mayors* - JRC, 2009) and low carbon urban form appears as an issue of their major interest.

Additionally, academic research shows that the characterization of carbon emissions from an urban system, although complex and demanding specific information (Cuchí, 2009), permits to portrait and then restrict, the carbon emissions of urban origin on a certain municipality, including buildings, mobility and sanitation emissions, and considering delocalized emissions (Figure 2 and 3).

This new quantitative knowledge allows to take informed options on territorial and urban form transformations, and to develop a balance between *high carbon* and *low carbon* urbanization. As research has shown, such balance does not depend only of urban form by itself, but also from micro factors as buildings envelope, or from macro factors as transportation infrastructure and open spaces structure and functions (Mourão, 2012).

Urban Carbon Balance is relevant for ecological territorial and urban form regulation but it is still not incorporated in an operative territorial and urban form regulation method. Indeed, traditional instruments of territorial and urban municipal planning cannot address energy urban demand neither urban carbon emissions. There are two main reasons for this limitation (Mourão, 2012): i) the regulation of carbon emissions at the municipality or city level demands methodologies and domains of information that not always are available or workable for urban planning (for example from IPCC reports, at the aim of Kyoto Protocol); ii) traditional planning relying on zoning fails to address key drivers of urban emissivity, such as mobility, sprawl or degradation and emptying of urban centres.

Figure 2. Urban carbon indicators for a Portuguese municipality (Source: Author, 2014 (data from 2007), Unities: Gig gram CO₂e 1.000 ton).

Figure 3. Urban carbon emissions distribution in a Portuguese municipality (Source: Author, 2013 (data from 2007)).

As shown before in this article, while defining areas for certain activities, *Garden-City* proposes a zoning segregating activities and groups, on a paradigm of full control of land uses, a trend that remained in the urbanism of the XX century (Mancuso, 1980; Voigt, 1989). *Low Carbon Cities*, instead, cannot be achieved through the segregation of activities, since they are inserted on a global logic and since they require performance planning, based on principles and goals for a certain territory, and not on the delocalization of emission sources.

An academic proposal for low carbon territorial and urban form regulation, applied to a Portuguese municipality (Torres Novas, 35.0000 inhabitants, figure 2 and 3), showed that territorial planning to reduce carbon emissions should follow principles countering high carbon actions inherent to unregulated urban growth (Mourão, 2012). These principles are: (1) polycentric concentration of settlements, refurbishing existing infrastructure and buildings, defining preconditions to allow urban transformations; (2) structuring low-emission mobility channels, integrating alternative forms of mobility and public transport, and anchoring this structure to the settlements; (3) safeguarding open spaces for water and waste ecological management, biodiversity and food provision, there controlling soil permeability.

At the academic research quoted, simple rules for urban built form planning were also proposed and tested at the scale of a 5.000 inhabitants settlement (figure 4): (a) use of winter solar gains and protection of summer solar gains in all buildings; (b) integration of pedestrian and bicycle paths connecting to the existing equipment; (c) definition of soil permeability rates and integration of reservoirs and pipelines for storm water.

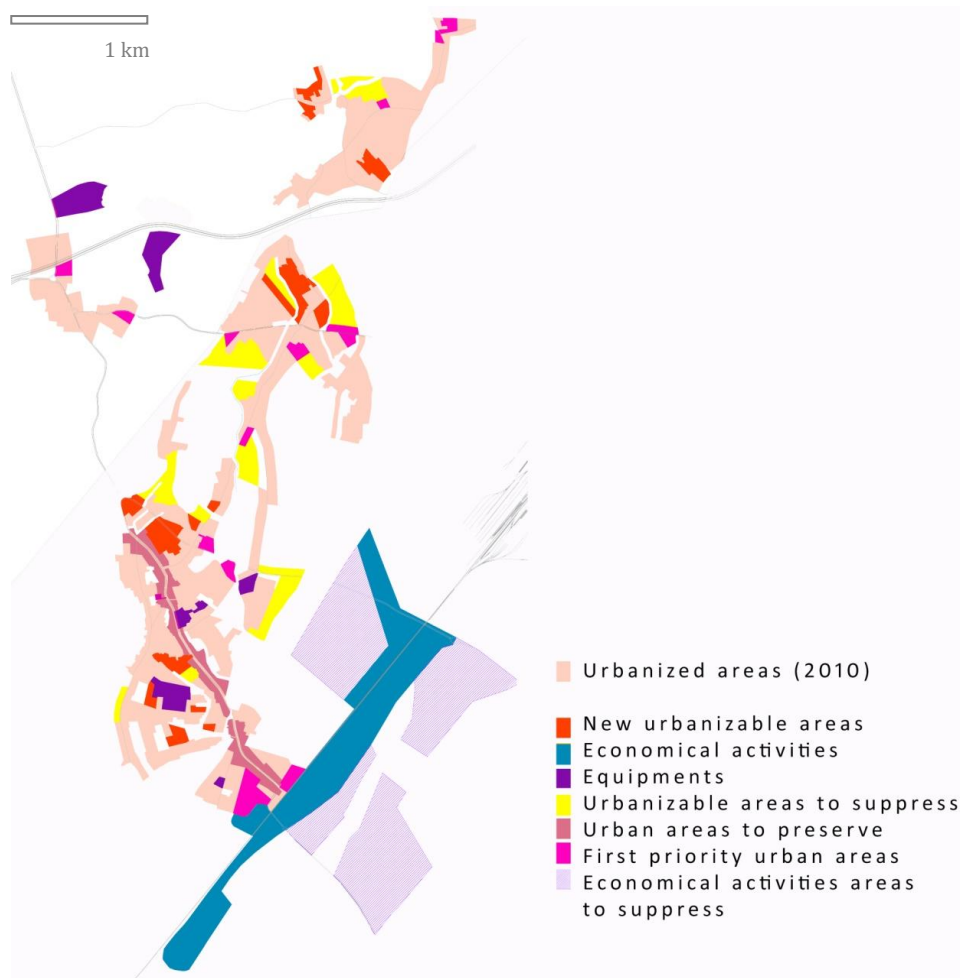

Figure 4. Ecological scenario for a low carbon settlement in 2020 (Source: Author, 2012).

This research has shown that with the framework of an ecological Master Plan, and a *Carbon Balance* quantifying and adjusting it in terms of emissions, it would be possible to require from the urbanization agents, in market economy, the compensation for the generated urban energy and carbon emissions demand. Thus, instead of a pre-established zoning, low carbon territorial and urban form follows pre-establish conditions and goals, which are converted in a ecological scenario of land uses and infra-structure adjustment (figure 4).

Discussion and Conclusions

“*Garden Cities of Tomorrow*” is a work with the ideological background of the local cooperative movement while the concept of *Low Carbon City* follows the ideology of “*Our Common Future*”, and the Earth Summit spirit of *acting local and thinking global*. Nevertheless, *Garden Cities* and *Low Carbon Cities* are comparable as *grassroots* territorial visions since both aim a superior ecological performance, urban pollution control and atmospheric emissions dispersion or reduction.

It is possible to identify several differences between these two urban visions, due to the *urban revolution* occurred during the time elapsed between the two moments when they were produced, as also due its inherent ideological and economical paradigms: while *Garden Cities* were linked to an social economy based on collective land and cooperative management, in times of urban and industrial expansion, being executed trough density and zoning regulation; *Low Carbon Cities* arise at the globalized market economy and industry delocalization. Its execution requires, instead, the definition of principles and rules for urban transformation, controllable by territorial local administration while facing global urbanization agents and major environmental changes. Such principles need to be legitimated by the recognition of environmental costs of urbanization (as carbon emissions) and its economic integration.

Garden Cities, as *Low Carbon Cities*, faced an economic and urban crisis, in different moments of History. Both visions intend to control urban growth trough territorial and urban form regulation, following the classical purpose of urbanism. *Garden Cities* were efficient on its environmental purposes because its spatial model, endorsed by the cooperative ideology, was able to structure urban development in times of strong urban dynamics.

Low Carbon Cities endorsed by “*Our Common Future*” face the harder challenge of structuring the territory in times of lower urban dynamics. As it was for *Garden Cities*, the balance between built and open space is a key for low carbon urban and territorial form regulation. However, in a globalized urban world, *Low Carbon Cities* will only succeed if the ruling of durable spatial structures is efficient to create a spatial context with low energy and carbon operation costs, at the long term and at a global scale.

Analysis of tools and ‘patterns’ for assessment of urban sustainability to promote design quality

Érika Otto, Liza Andrade, Natália Lemos

Faculdade de Arquitetura e Urbanismo, Universidade de Brasília, Brasil.

lemos.natalia@gmail.com.

Abstract. *This research on methods and requirements to forward urban environmental regeneration aims to investigate the requirements and patterns of assessment of urban sustainability in the process of urban design. In the environmental certification of urban development, there is a wide range of evaluation methods developed and disseminated by various countries and organizations. In Brazil, the main evaluation methods used are classificatory, and, although with different criteria the quantitative system is the norm to achieve the certificate. None of them deals directly with the spatial shape or patterns as qualitative parameters of architectural and urban design. This methodology aims at urban environmental regeneration, it integrates studies of ecological urbanism principles for resilient cities (Spirn, 2011) and the principles of urban environmental sustainability (Andrade, 2008), connecting them to the “patterns” developed by (Alexander et al., 1977) and identified by (Moehlecke, 2010). The patterns illustrate strategies for the design process, offering alternatives that lead to the design of more sustainable human settlements. For an in-depth examination, the research analyzed the BREEAM Communities method (UK). This method was juxtaposed to the 108 patterns selected by (Moehlecke, 2010) leading to satisfactory results matching the criteria in sustainability categories within social, economic and environmental dimensions.*

Key Words: Urban regeneration, sustainability principles, urban patterns, environmental certification

Introduction

The evaluation of urban sustainability is a complex theme that has different approaches in different countries. Diverse economic contexts and environmental laws lead to a range of methods for environmental assessment, each adapted to its local conditions. In Brazil, international methods are often imported and it is important to question their applicability to local circumstances.

In Brazil, certifications are being used increasingly to incorporate marketing value and are becoming a powerful tool for real estate development. This has the benefit of attracting the attention of society to the issue of sustainability. However, in most cases, the issue of social justice is not taken into consideration.

Models of sustainability certification in urban areas have evolved significantly in the last few years. The main evaluation methods in Brazil are classificatory, such as the LEED-ND certification - Leadership in Energy and Environmental Design for Neighborhood Development, developed by USGBC - United States Green Building Council and the High Environmental Quality standard (AQUA) to Neighborhoods Allotments and adapted from the French HQE technical reference - Haute Qualité Environnementale.

The sustainability principles used in LEED-ND were extracted from policies for sustainable urban development (Smart Growth and New Urbanism) to neighborhoods, development of urban communities and sustainable construction (Green Buildings) integrating principles of smart growth and planning for sustainable construction designing neighborhoods. The criteria adopted by LEED-ND are divided into three categories: a) smart location and linkage, b) neighborhood pattern and design and c) green infrastructure and buildings.

The High Environmental Quality (AQUA) for Neighborhoods, method was adapted from the French HQE technical reference - Haute Qualité Environnementale to Brazil by Vanzolini, from the University of São Paulo. The Technical Reference presents criteria grouped into three categories: a) neighborhood integration and coherence; b) neighborhood natural resources, environmental quality and health, and c) social life and economic dynamics.

The first national sustainability classification system developed in Brazil, the *Selo Casa Azul da Caixa*³⁵, was created in 2009 and sought to associate the budget restrictions and social practices across six categories: urban quality, design and comfort, energy efficiency, resource conservation, materials, water management and social practices. However, the method does not comprehend urban design, being limited to the evaluation of urban sustainability.

Despite establishing requirements for achieving urban sustainability from the earliest stages of project planning, these certifications do not directly address the urban form and spatial patterns that serve as parameters of quality in architectural design and urban planning. All these methods are quantitative approaches to classification systems, used exclusively for certification. Considering the social inequalities in Brazil, it is necessary to analyze the tools and assessment patterns of urban sustainability that can promote both urban environmental regeneration and quality of urban design, as well as the applicability of the foreign methods of environmental certification within the local context.

The certification of BRE BREEAM Communities (UK), not yet translated into Portuguese, was emphasized in this research for further studies due to its application process that serves as a framework for urban planning and design. This guide encompasses design parameters that guarantee models/patterns that promote social and economic benefits, mitigating the impacts of the built environment in eight categories of sustainability: energy and climate, site modeling, community, ecology and biodiversity, transport and mobility resources, businesses and buildings.

This research hypothesizes that if these models of certifications are combined with spatial patterns of sustainability they can be a guideline to quality in urban design.

As a methodological procedure, initially, in order to understand urban environmental regeneration, we studied the principles of ecological urbanism for resilient cities (Spin, 2011). Within the principle "cities are habitats", patterns were identified (Alexander et al., 1977) as parameters of quality in architectural and urban projects, and recognized by (Salingaros et al., 2010), as a way to generate codes for design tools. Then, sustainability principles (Andrade, 2005 and Moehlecke, 2010) were juxtaposed with "patterns" of quality in design. Although not aiming specifically at sustainability principles "A Pattern Language" offers strategies in the form of tools applicable at different levels of the physical environment, leading to the development of more sustainable human settlements. Lastly, after understanding these patterns, we assessed the tools in the Evaluation of Urban Sustainability (ASU) and its requirements and criteria of sustainability, seeking to compare and combine them to the sustainability patterns in BRE - BREEAM Communities, matching its criteria to patterns and sustainability principles.

Theoretical and methodological aspects

Society and the current economic model, powered by exhaustible natural resources, increase reveal themselves to be increasingly unsustainable. This model is being pushed towards a sustainable evolutionary trajectory, which raises the need for new propositions and future adaptations.

(Spin, 2011) presents ecological urbanism as a solution to degradation caused by urban settlements. Ecological urbanism integrates theory and practice of designing cities with urban planning and ecology and other disciplines, studying the relationship between living organisms

³⁵ The Guide *Selo Azul da Caixa* was developed by a CAIXA technical team, with support from a team of specialists from the universities USP, UNICAMP, and UFSC.

and their environment. It defines some principles that allow the coexistence of all relationships between management systems of city and nature. (Spirn, 2011) describes six principles for resilient cities, defining them as: (1) part of the natural world, (2) habitats (3) ecosystems (connected and dynamic), (4) a deep structure or (5) examples of support, and lastly, (6) urban design as an adaptation tool.

A Pattern Language (Alexander et al., 1977) falls within the principle "Cities are habitats" that should provide its residents the social and biological needs, in which the survival of the species is related to the equilibrium and control that resultant from the design of their habitat. Therefore, urban design meets "habitat quality", promoting and enhancing the development of processes supporters of life and satisfactory to the needs of living beings.

(Alexander, 1979) in "The timeless way of building" identified a precise and objective quality within the built environment, "a quality without a name", that once achieved, injects hope of life in what we build. This quality gives life to things, freeing them of internal contradictions and consists of a complex system that demands fealty to its own nature. It can be partially expressed by some limited words such as: lively, whole, comfortable and accurate.

(Alexander, 1979) describes a process that, if allowed, reveals the spontaneous order in each of us, resulting in the possibility of designing good and agreeable places, and building lively structures. On the other hand, when fear prevents us from finding that order we follow rules that result in dead places.

In defining this quality in buildings and cities, it is important to understand that a space gets its character by patterns of events that happened within it. It is connected to these events and, although not limited by it, an event is also the space where it happened. Patterns of events always relate to certain geometric patterns of space, allowing an analysis of what he calls spatial patterns.

This analysis shows that in buildings or in urban areas there are recurring elements, and recurring relationships among them. These elements combine in different results and variations with different patterns of relationships. The element is, in fact, the pattern of relationship established between the element itself and the elements of the surrounding world.

Therefore, a space would not be formed by elements initially identified, but by patterns of relationship indicative of its character. Patterns are concrete elements, solid substance and starting points to create a building or a city. In adopting living patterns, the outcome is the spatial quality. Hence, it is recommended the use of "patterns with the quality without a name" in order to design a good project.

From this premise, Alexander and his team proposed a language made of a set of patterns. It identifies qualitative guidelines, resulting in patterns that compose a language for urban and architectural design, promoting an environmental quality and "a timeless way" to build. The result is a universal process that preserves quality throughout time, a way to build and design that can help designers to determine the structure of urban spaces with a whole and integrated outlook (Alexander, 1977).

The patterns are presented and distributed according to their different scales, ranging from more global aspects to the construction details. All of them were observed over a long period of time in spatial characteristics of successful places totaling 253, capable of forming an infinite variety of combinations. As the nature of the construction process is understood, a language made of patterns becomes possible. Each pattern relates to the other in order to complete major and minor patterns, many interconnected, suggesting a fundamental order to the working of the language.

The result is a linear sequence from the larger to the smaller scale, revealing a fundamental worldview, which does not build one thing alone, but acts in the world around it and within, allowing for a broader and holistic coherent vision of the world.

The language is more than a manual. It consists of a core archetype of all possible pattern languages, capable of making individuals feel alive and human. By adopting these patterns as the basis of analysis, we focused on understanding its system so that we could connect them to urban sustainability assessment tools.

Patterns and Principles of Environmental Sustainability

Despite the existence of guidelines for more sustainable urban settlements, the recommendations are usually quite general, lacking studies on urban patterns, a tool that could greatly contribute for sustainable development. (Moehlecke, 2010) saw in the book "A Pattern Language" by Alexander et al., an opportunity to study patterns connected to sustainability, although not formulated specifically for this area. The patterns can be seen as strategies potentially able to contribute to the sustainability of urban settlements.

To the urban patterns identified in the work of (Alexander et al., 1977), were juxtaposed sustainability principles based on several authors, among them (Andrade, 2005).

These principles are of common interest to different societies and can be applied in different contexts, as well as guide the development of desirable characteristics.

The results of theoretical connections and analyzes was a set of 108 urban patterns distributed within nine principles of sustainability in social, economic and environmental dimensions present in human settlements. The scales chosen go from the smaller scale of the place, then the neighborhood, to the largest scale of the settlement.

The principles organized by (Moehlecke, 2010) are a result of the translation of "key ideas" (themes) taken from the matrix composed by the dimensions of sustainability (environmental, social and economic) and the three urban scales (place, neighborhood and settlement). Each urban scale, according to the author, must be represented by three principles, each being representative of a dimension. The result is a set of nine principles: social interaction, urban diversity, mixed land use, biodiversity, habitability, compactness, energy efficiency, sustainable mobility and local economy. This identification is only introductory, as other principles can be incorporated later.

Thus, the set of patterns that establishes a connection with the issue of sustainability takes the form of intervention strategies and tools that could be applied in different levels of the physical environment, allowing human settlements to develop more sustainably. The criteria used to establish these connections are: the dimensions of sustainability, the urban scales, and the principles of sustainability.

Both the criteria and the patterns selected provide a base for the analysis of environmental certifications and indicate, respectively, if the certification is truly sustainable and if this is reflected in the quality of the urban design. Each pattern was analyzed considering its relationship with a certain principle and its contribution and potential contributions to other principles and dimension of sustainability, as a pattern can contribute in more than one of them. Therefore, it was possible to connect the patterns of sustainability identified by (Moehlecke, 2010) to the criteria of environmental certifications, in this case the criteria of BREEAM Communities.

Breeam communities

The BREEAM Communities is an independent organization within the family BREEAM, which uses third party assessment and certification standard based on BREEAM methodology. This method consists of a framework for analysis of issues and opportunities that affect sustainability in the early stage of the design process and development.

Developed by BRE Global UK organization, the BREEAM accreditation system for city planning presented its first pilot version in 2008 (almost 20 years after the first versions BREEAM for buildings). Previously, the organization developed a manual for planning and design at the urban scale that was the basis for the requirements of the certification system. Between the 2008 version and the final document, the certification system has undergone public revisions to allow for public participation in the context of urban planning.

According to BRE organization, this certification has four specific objectives: reduce overall impacts of urbanization; recognize projects and communities according to their environmental, social and economic benefits; provide an accredited label for urbanism focused on sustainability; and stimulate demand and ensure the effective development of sustainable communities. The aim is to build a vehicle to support the development of projects ensuring that the models/patterns promote social and economic benefits, mitigating the impacts of the built environment.

Therefore, it uses measures of quantification/evaluation for sustainable determinations with flexible approaches, avoiding specific requirements and solution of composition. It uses the best available science and practice as the basis of qualification and calibration, cost-effective models/patterns for the definition of sustainability, and aims simultaneously for economic, social and environmental gains.

The environmental assessment methodology is extended to the holistic view of sustainability, considering the social and economic impacts of development. It is expressed in a system of negotiable credits divided into three steps. The steps and the organization of the guide help project managers in integrating master planning with evaluative processes and ensure the addressing of issues at appropriate times in the planning process, absorbing strategies of regional sustainability and encompassing environmental, social and economic planning issues.

The issues addressed in the manual are grouped into five impact categories as mentioned above. The criteria relevant to each step of these categories were developed in the following discussion.

Results of the correlation of breeam issues with sustainability patterns

These categories indicate a direction for sustainability, but do not provide an indication of how to actually achieve it. They outline a goal, without showing the way. The issues assessed are generic and can be accomplished without guaranteeing the quality of design and even urban sustainability in full, functioning only as a checklist.

However, by correlating the BREEAM criteria to the contributions of sustainability patterns, we obtain a design methodology, as the patterns direct how to reach the final goal. The sustainability pattern groups contribute to the issue selected by (Moehlecke, 2010) within the dimensions of sustainability. Through these contributions, a way to correlate BREEAM issues to sustainability patterns was developed, as shown in the following table:

Table 1. Issues, contributions, patterns of sustainability

ISSUES ASSESSED	ISSUES / CONTRIBUTIONS	PATTERNS OF SUSTAINABILITY
GO 01 - Public consultation plan	Not addressed in the patterns selected by Moehlecke (2010)	p.45 Necklace of community projects (Not among sustainability patterns selected)
GO 02 - Consultation and engagement		
GO 03 - Project Analysis		
GO 04 - Community management of facilities		
SE 01 - Economic impact	Support for local farmers Support for local products	p.19 Web of shopping, p.32 Shopping street, p.87 Individually owned shops, p.89 Corner grocery, p.93 Food stands,

		p.177 Vegetable garden
	Strengthen local commerce	p.6 Country towns, p.46 Market of many shops, p.165 Opening to the street

The results showed that no items relating to the criteria in the governance category were found and therefore no pattern of sustainability applies in this category according to (Moehlecke, 2010). However there are patterns concerning community projects consistent with Alexander. In the category of social and economic well-being (SE) 27 out of 36 issues were found, contributing to all the principles of sustainability (Moehlecke, 2010). In the category resources and energy (RE) 16 issues were identified, and apply to the principles of urban diversity, habitability, energy efficiency and sustainable mobility, embracing the three pillars of sustainability.

In the category of land use and ecology (LE) 12 issues were identified, contributing mostly to the principle of biodiversity, as well as other principles such as mixed land use, urban diversity, social interaction, habitability and compactness. No mention of the principles in the economic dimension was found. Lastly, in the category transportation and mobility (TM), only the issues of the principle of sustainable mobility were considered.

Final considerations

The research showed that patterns and their contributions according to (Moehlecke 2010) can be connected with environmental certification procedures because they share a common base in the triple foundation of sustainability. In the study of BREEAM, more categories of sustainability were found to be met, which shows the scope of studies by (Moehlecke, 2010) concerning the certification procedure. Although some of the issues assessed were not discussed by the author, it is possible to employ patterns (Alexander et al., 1977) in order to achieve the necessary theoretical support.

(Alexander et al., 1977) also argues that the pattern language allows for the creation of new patterns, in case the ones described are not sufficient. These new patterns should be extracted from the natural order of things. The inclusion of patterns, as suggested for BREEAM, can be done as well for other environmental certifications, leading to better quality in urban design.

Abstract. *The study of the complex dynamics that engage urban form presents powerful instruments to understand the driving forces of contemporary urban development. This research intends to test traditional urban growth tendencies against informal development mechanisms and decision-making behaviors of competition in geosimulated environments. The empirical objectives are the investigation of the morphological patterns of peripheral poverty and its interactions with urban form, in which accessibility has played important parts sided by informal processes from Latin-American contemporary cities. The paper will present a theoretical review of agent-based models in cellular environments stressing urban growth and decision-making processes as basis for a proposal of a hybrid agent-based model in cellular space. The contemplated model expands the cellular automata approaches by including the interpretation of the model's landscape by heterogeneous collective agents that settle and promote growth in competitive dynamics according to preferences and hierarchy. The expected result is an urban development intensities landscape, natural features and agent-types concentration, which should allow one to analyze urban form expansion and fragmentation, socioeconomic segregation and urban policies effects. This work succeeds the research by the LabUrb/UFPEL based on the CityCell modelling framework, which has yielded insights on the linkages between urban morphology, social and environmental attributes through emergent urban phenomena simulation focused on temporal and spatial dynamics.*

Key Words: *Urban Morphology, Urban Growth, Social Process Dynamic Simulation, Cellular Automata, Agent-Based Models.*

Peripheries, urban form and contemporary urban development

Cities make up the largest artifacts made by man and have structured human organizations since the first agricultural sedentary societies 6,000 years ago in Mesopotamia (Portugali 2000). Over history, humanity has become dependent on cities for its subsistence and as cities developed and evolved the growing integration of its inner and outer expansion converged. In contemporary urban development dynamics, important economic and social feedback mechanisms reinforce this bond. Urban form is, therefore, composed through interactive cycles in which both the peripheries and its centers have active roles (Barros 2004; Abramo 2012).

By end of the 20th Century, the urban development process, propelled by economic and cultural globalization, has led the peripheries to the forefront of urban development research. The transition processes that had started in the Industrial Revolution consolidated by changing morphological patterns worldwide and cities could no longer be defined as the compact *intramuros* built mass that exercised absolute contrast with the country surrounding it. Modernity brought about the progressive dissolution of the urban block (Panerai et al. 2004), while post-modernity intensified the dispersal of the urban tissue, its hybridization and the introduction of diverse intermediate stages of urbanization (Chin 2002; Ascher 2010).

The fringes of cities were the stages where sizeable part of this processes took place. The disperse outskirts and the *terrains vagues* from the *arrebaldes* were gradually settled in, assimilated by the overall urban form and overcome in cyclic expansion waves. From the centers outward, city form blended with rural and semi-rural forms, discontinuities and low

densities. It was crossed by vast transportation networks and divided in extensive polynucleated urban areas. The city limits became less clear with the stretching of urban form, as if the city was distended to the point of being penetrated by less dense land uses so that towns begun to blend with one another, forging continuous occupation gradients of varied densities (Chin 2002).

These changes endowed contemporaneity with great diversity of urban forms that elude apprehension and classification. On developed countries, specialized urban nuclei organize vast mono-functional suburban networks. This sprawling urban form expands into very low density and extends as far as the fuel price allows, while urban inhabitants gradually abandon the inner city districts (Berube & Kneebone 2006).

South of the Equator, immense informality and poverty areas are interspersed with industrial facilities and high income enclaves (Davis 2004); social inequality soars and informality is incorporated as the main alternative to access urban land for poor families (Bógus & Taschner 1999). A true urban development kaleidoscope (Abramo 2012) is formed and redefined in continuous cycles, without ever solidifying and keeping permanent impetus towards expansion (Barros 2004).

In this fractured urban condition, the informal settlements scale is such that they start amassing relative autonomy from the regular urban processes controlled by regulations and promoted through the market. They create para-formal logics that escape the normative discipline of the rule of law and work around environmental and infrastructural constraints. Their urban interventions are brought about through family savings, reciprocal relationships and local trust networks (Davis 2004; Abramo 2012). This process establishes a peripheral condition: the co-existence of opposites with little compatibility; the interspersing of compact and disperse urban forms; the connection of specific sites to the global scale and the segregation between adjacent territories based on class; overall low densities; close relation to informality and blatant illegality; and settled extensions that converge to the regional scale (Walker 1978; Polidori 2004).

This spatial differentiation presents the close combination between the formal market and widespread informality. The stock market bound real state is associated with land grabbing practices, with self-help housing in *favelas*, with the popular occupation of urban voids and derelict inner buildings. Since the externalities of one process is captured by the other, the interaction between space and social processes driven by diverse rationalities imposes antagonistic, but reciprocally determined tendencies. Dispersion and concentration of urban form occur in alternate cycles propelled by the land market's logic as well as by necessity's vigor (Abramo 2012). They reveal important systemic ties between the urban territory and multi-scale heterogeneous agent and process networks (Barros 2004).

Global and urban peripheries

In contemporary urban growth processes, cities serve as conduits and motors to globalized capital so that the capitalist processes at work over land and places (Harvey 1978) include the cities as translators of global dynamics to the diversity of local reality (Scott & Storper 2003; Sassen 1999). The contrast between global city-regions and global peripheries is reinforced under global stimuli and in response to local characteristics. The world-economy capitals are organized around their specialized and increasingly anti-human Central Business Districts (Davis 2006) and diametrically oppose immense portions of territory excluded from the capitalist mode of production and its control (Davis 2004). The latter lie on the extreme end of civilization: they are relegated to material inferiority, absence from rule of law and to the deprivation of means for their autonomy.

In the middle ground to these extremes, human societies are pushed towards polarization. While some of its members increase their specialization, others have to make the best of informal labor as the only available route for inclusion (Bógus & Taschner 1999). In Latin-

American cities, in the decades of 1950-1960, informal areas were ignored and if possible removed (UN-Habitat 2010). More recently, though, one can see the resurgence of informal peripheries as majoritarian form of urbanization and shelter for most of the population, especially from the 1990s onwards (Bógus & Taschner 1999; UN-Habitat 2003). What remained was the overall state of incomplete infrastructure, lack of basic services and opportunities, portraying a second-class urbanization (Davis 2004).

In the last two decades, the urban outline is defined: more than half of the world population becomes urban, largely due to the contributions of the borders of urbanization on the edges of cities of peripheral countries in globalized economy (UN-Habitat 2010). These sites, in dual peripheral condition (both global and local), become the object of renewed interest as a tool for explaining the urban question integrally through the provision of intermediate and varying tones of a continuous spectrum of urbanization (Chin 2002).

The role of the peripheries

In third-world cities, the phenomenon of social inequality proliferates fueled by segregation based on spatial disintegration (Bógus & Taschner 1999). This happens not as a secondary consequence of the capitalist development of cities, but as a central mechanism of its reproduction (Harvey 1978). The expansion of cities according to economic and productive stimuli occurs on alternate surges of rapid, disorganized and seemingly chaotic expansion, which are followed by slow, gradual consolidation. In these cyclic processes of capitalist urban development, poverty areas act as compensation valves to cities' expansion mechanisms. They dampen tensions, absorb environmental impacts and infrastructure costs while maintaining flexibility to change according to the settlement evolution. Thus, it can be argued that the precarious and unstable occupations "[...] actually absorb part of the existent social instability [...] in unstable pockets within the city" and that "[...] they are necessary for the structural stability of the global system." (Barros 2004, p.180).

The actual development of Latin American cities is connected to socio-economic inequality. It reinforces it, but is also fueled by it. From colonial times the political and legal frameworks have privileged landowners, which in turn heavily influences the locational process and has pushed the larger part of the population into the informal land market. Contemporarily, capitalism is interwoven with these traditions and composes a complex system of competition, complementation and superimpositions between the legal and informal land markets. While the individual location decision from a family may target the optimization of its choices, the aggregate effect is a conflicting tendency among similar families: while searching for unique opportunities, they drive the market towards homogeneity, which narrows their choices. On the bottom of the social scale, poor families are driven outwards towards the cheaper lands of the peripheries and lesser opportunities, or have to improvise ever-denser inner-city settlements. The conflicts are broadened by social segregation resultant from the "urban convention" that draws middle-class families towards places occupied by families of similar, or higher, social standing, leaving the poor to fend for themselves in self-help, informal support circles (Abramo 2012).

This rationale seeks to expose non-aggregate behaviors that are relevant in the modes of production and occupation of the urban form, acting either in coordination or in competition with the general market mechanisms. The reciprocal influences between formality and informality are based on local externalities and logics of interpersonal knowledge and trust, which add up in consecutive cycles of valuation and de-valuation of urban form (Abramo 2012). This shapes cities through inter-representation networks (Portugali 2000) between urban morphology and socio-economic processes that reveal emerging patterns of "peripherization", which is the alternation between compact and diffuse urban form. These processes increase contrast between city center and periphery and stress the marked social differences of Latin

American societies: the poor end located in the expansion edges or in dense favelas, while the better off live near the city center and public services.

Urban periphery models

Geosimulation supports an embryonic “science of cities” (Batty 2012) that seeks to reveal patterns of order that emerge from actions and decisions where individuals interact with their environment and to each other in collaboration or competition, from the bottom of the systems up (Batty 2007). Urban models in cellular environments have relevant capabilities in describing city growth under these premises (Batty 2007) and urban Cellular Automaton (CA) models allow to coherently articulate the effects of urbanization on the natural environment (Polidori & Krafta 2005), on informality and on poverty formation (Barros 2004; Patel et al. 2012). The simulation of urban dynamics can be achieved through the interaction of adjacent cells in grids that changes states following simple rules, applied locally and in repetition, under stochastic *disturbances*. The accretion of these neighborhood relations is capable of producing order states that emerge from the bottom up, correlating basic elements from the urban environment that shape overall system order (Batty 2007).

Cellular models of urban growth can be further complemented by the explicit inclusion of social agents as these may simulate the decision-making capacity of rationally autonomous entities with limited knowledge. Agent-based models (ABM) bring the detailing of each agents characteristics to enable the modeling of particular behaviors and attributes such as motivation, objectives, goals, decision-making and learning. The combination of cellular environments based on CA and autonomous decision making from ABM may be used to represent social processes articulated to morphological dynamics (Heppenstall et al. 2012).

Agent-based model of peripheral growth

This paper proposes a model that aims to answer questions of location choice, competition and exercise of power in decision-making processes. These processes are executed by non-coordinated social actors during urban external growth in dynamics that put relate urban form to social interests, as demonstrated by image 1.

This research is supported by the CityCell modeling framework, through which initially Polidori (2005) and more recently Saraiva and others (2013) have produced several urban growth simulation models on cities from southern Brazil. Following to the frameworks’ structure, the modeling environment is defined by urban, natural and institutional attributes (

figure 3). They are represented in different intensities on a grid of square cells and can have behaviors of attraction or resistance to urbanization, interacting in accordance with local rules to simulate urban growth processes (Polidori & Krafta 2005).

Figure 2. General model flowchart.

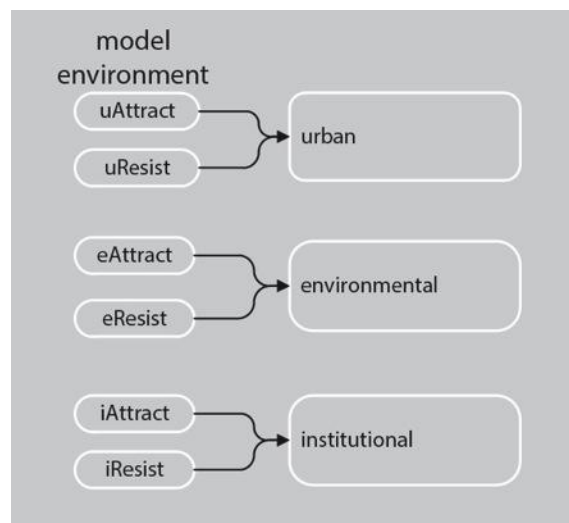

Figure 3. Modeling environment structure consisting of urban, environmental and institutional attributes, which offer attraction or resistance to urbanization.

The society that populates the model consists of autonomous agents capable of decision-making. The agents' categories represent social groups defined by socioeconomic profiles such as social classes. These agents dwell exclusively on urban cells, and may choose to move according to their preferences. This model constitutes a hybrid approach between the fully explicit individual ABM and the implied social behavior contained in traditional CA models.

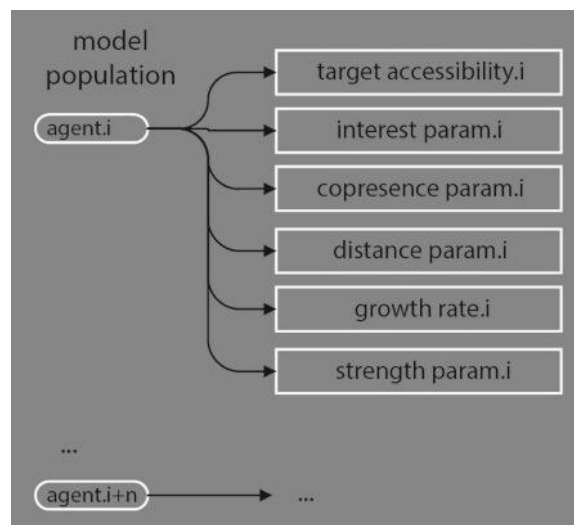

Figure 3. Agents' parameters.

To determine the agents' evaluation of the environment, movement and competition dynamics, as depicted in

figure , agents have the following parameters: (a) *target accessibility* (Av): is the value of relative accessibility (see below) considered optimal by the agent. In its evaluation of environment cells, the agent checks the available range of relative accessibility (from cells in its neighborhood) and chooses the cell that most closely matches its *target*; (b) *interest parameters* (w): are the stated preferences for each agent in relation to the environment attributes and accessibility. They take the form of multipliers to be applied when composing the *Interest*

Matrix (below); (c) *interest matrix* (T): is the combination of interest parameters for each agent and attributes of the model. It is calculated in every cycle, being sensitive to variations from unstable attributes, accessibility and urban area growth; (d) *copresence parameters* (c_p) indicate the tolerance to different agent populations in the same cell as a given agent. These parameters are the base for the copresence threshold on each cell, concerning each pair of agent settled on it. They increase the tolerance to different agents' populations in direct proportion to its value; (e) *strength parameter* (s_p): implies the ability of an agent to exercise power in the competition process. It influences in determining the expulsion of agents when the copresence threshold is overcome in a cell as the "leverage" each agent can use against its opponent. The parameter influences disputes in direct proportion to its value; (f) distance parameter (d_p): is the maximum distance, in number of cells, that an agent is able to go (or see); (g) growth rate (θ): is the growth rate per cycle of each agent. By default, equals the growth rate of urban cells, but can be specified for each agent separately.

Model dynamics

The overall dynamic structure of the model starts with the entry of environmental and social data in the model. This includes the input of urban areas, the initial distribution of agents' and other attributes in the form of two-dimensional data grids, as seen on figure 4.

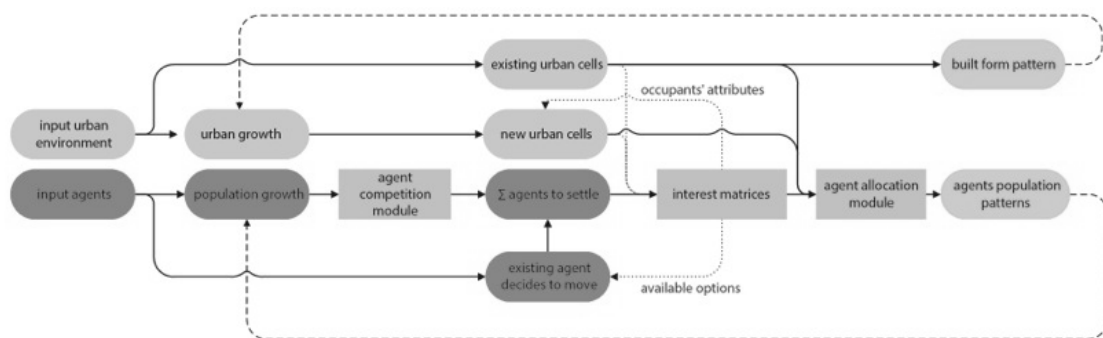

Figure 4. Model dynamic structure.

The first step after initialization is urban growth, which derives from a weighted accessibility measure from Saraiva (2013). In this model, it acts as a subroutine that determines distances among cells loaded with urban attraction that receive “resistances” from environmental attributes (increasing relative distances) to generate an global accessibility pattern. This pattern is then normalized and used as the base for a combination of deterministic and random mechanisms that distribute fixed rates of urban growth, as expressed in Table 1.

The main stage of the agents decision-making process depends on the intersection of agent's preferences with the modeled environment. The agents' potential choices are represented in the *interest matrix* (T), determined from each agents' interest parameters (w) related to the model attributes (A).

For urban, institutional and natural attributes to be included in the *interest matrix*, they need only to be informed and have their weights defined during input. Accessibility, however, must be checked against the economic power of the agent, comparing *target accessibility* (A_v) to *relative accessibility* (A_r) in tandem with the agent's interest on accessibility. The highest values of relative accessibility are close to 1, while the lowest approach 0. The target-accessibility varies within the range of A_r , and therefore has values ranging from 0 (the least economic power) to 1 (the highest economic power). The relationship between the target

accessibility of the agent and relative accessibility of each cell is given by the *particular accessibility* (Ap) measure, as expressed in Table 2.

Table 1. Cell i accessibility.

$AC_i = \sum_{(j \neq i) \in U} \frac{1}{d_{ij}}$	Where: AC_i = cellular accessibility from cell i d_{ij} = distance between cells i and j U = cell set loaded with urban attraction attributes
$d_{ij} = \sum_{c \in C_{ij}} Env_c$	Where: d_{ij} = distance between cells i and j Env_c = cell c weight for the weighted accessibility measure C_{ij} = preferential path cell set between i and j
$Ar_i = \frac{AC_i}{AC_{max}}$	Where: Ar_i = relative accessibility from cell i AC_i = cellular accessibility from cell i AC_{max} = maximum <i>grid</i> cellular accessibility

Source: Saraiva (2013).

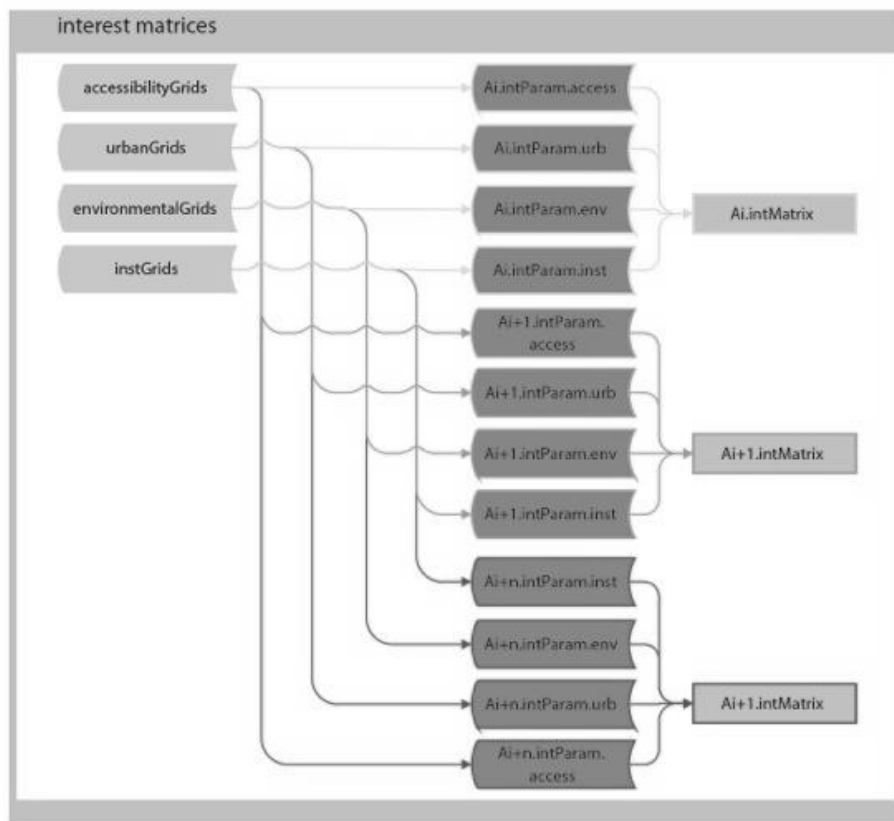

Figure 5. Modeled attributes and relative accessibility form the *interest matrix* for each agent.

Table 2. Particular accessibility for the agent i in cell (x, y) .

$Ap_{i,x,y} = 1 - (Av_i - Ar_{x,y}) $	Where: $Ap_{i,x,y}$ = Particular accessibility for the agent i in cell (x, y) and $(x, y) \in Cd_i$ $Ar_{x,y}$ = relative accessibility of cell (x, y) Av_i = target accessibility from agent i
--	--

Table 3. Agent i interest matrix.

$T_i = \sum_{(x,y) \in Cd_i} t_{i,x,y}$	Where: T_i = is the interest matrix for agent i , drawn from the t_i parameters for every (x, y) cell, and $(x, y) \in Cd_i$
$t_{i,x,y} = \sum_{j=1}^m w_j A_{j,x,y} / \max \left(\sum_{j=1}^m w_j A_{j,x,y} \right)$	Where: $A_{j,x,y}$ = model attributes present in (x, y) cell w_j = each attribute's weight set by the equivalent <i>interest parameter</i> m = number of attributes taken into account.

The sum of all preference measures (t_i) compose the interest matrix (T_i) for the i agent, as in Table 4.

Each agent's decision to move for can take two forms: voluntary or due to competition for a certain space. In the first case, the *interest matrix* subsidizes the decision-making of agents, defining a "topography" of its preferences in the system's cells that is compared with the cell the agent occupies in each iteration. If the current cell is below the average, the agent then decides to move.

In the second case, it is assumed that even if the urban form does not impose a settlement limit to the agents (such as a finite urban form stock to be allocated), there is constant contention over urbanization. The occupation tolerance of each agent's surroundings to different categories of agents is geared to this contention. The limit for this "tension" between the agents is defined (for each of them) by its copresence parameter. This parameter enlarges or reduces the quantity of different agents to be tolerated in the same cell, as shown in table 4. It should be noted that the co-presence factor is directional, i.e., there may be differences between the parameter of agent i to agent j to the parameter of agent j to agent i , indicating asymmetry in co-presence relations.

Table 4. Co-presence test from agent i to agent j .

$Cf_{i,j,x,y} = \frac{P_{j,x,y}}{Cp_{i-j} \times P_{i,x,y}}$	Where: $Cf_{i,j,x,y}$ = copresence factor from agent i to j in (x, y) cell $Cp_{i,j}$ = copresence parameter from agent i to j $P_{i,x,y}$ = agent i population in (x, y) cell $P_{j,x,y}$ = agent j population in (x, y) cell
$Cpres_{x,y}(Cf_{i,j,x,y}) = \begin{cases} true, & Cf_{i,j,x,y} \leq 1 \\ false, & Cf_{i,j,x,y} > 1 \end{cases}$	

Experiment for Jaguarão/RS/BR

Jaguarão, in the Rio Grande do Sul state of southern Brazil has been studied by the Laboratório de Urbanismo³⁶/UFPel in recent years. Outreach initiatives, undergraduate education and research have been conducted in a systematic manner and have provided important data on the municipality. Therefore, in continuity to some of this research, this experiment is set to verify the following hypothesis: is there influence from disaggregate decision in settlement patterns, especially when poverty is considered?

Figure 6. Modeling environment. Jaguarão/RS/BR urban área Quickbird image from 2009 superimposed by 200m celular grid.

This issue serves as a base for future investigation and model development. To address it and to verify the viability of the current proposal, the experiment is outlined as follows: (1) to simulate urban growth in the CityCell framework making use of agent-based model over the weighted accessibility from Saraiva (2013); (2) to consider the agents distribution from urban, natural, and institutional attributes and accessibility influence as a result from agent allocation decision making; (3) to verify the selected attributes influence, seeking evidences of the linkages between morphological attributes and social subjects.

The parameter set for the urban growth dynamics can be found in Table 5.

Table 5. atributos de entrada do modelo de acessibilidade ponderada por fatores ambientais

Atribute	Type	Weight
1947 urban nucleus	urban/attraction/mutable	1,0
Rio Branco (UY) municipality	urbano/attraction/freezing	0
Jaguarão river	urbano/attraction/freezing	0
Watersheds	natural/resistance/mutable	0,7
random layer	natural/resistance/mutable	0,3

Figure 7. model attributes; a) effectively urbanized area in 1947; b) the territory of Rio Branco, Uruguay; c) Jaguarão river; d) watersheds (dark values are the valley bottoms and clear values the watershed limits); e) random layer; f) roads. (Source: Saraiva).

The modeling environment was established in a GIS in the UTM geographical coordinates system, zone 22 south. It encompasses the extended surroundings of Jaguarão urban area in 2009. It results in the rectangular area shown in

Figure 6, which is divided into 1,476 cells of 200x200m. The growth simulation attributes are shown in Image 7 and its results are the growth patterns illustrated in Image 8, for iterations 01, 11 and 31 (corresponding to the 62 years from 1947 to 2009). On the left column is the resulting urban form for each iteration, while on the right, there is the relative accessibility patterns.

Interest matrix

Three agents' categories are set for the model population. They represent the high, middle and low-income populations on the city and to each a parameter set was assigned, as shown in table 2. For this experiment, their preferences were determined by the modeler according to relevant cases from the literature, considering income stratification, the road system influence, as well as relationships with environmental attributes, topography and non-urban land use (Sietchiping 2004; Augustijn-Beckers et al. 2011; Abramo 2012; Heppenstall et al. 2012).

Table 6. Agent attributes.

agents	accessibility		urban		environmental		
	target	interest	nucleus	roads	Jaguarão	watersheds	crops
			1947		river		
low income	0,2	3	3	9	1	3	3
average income	0,6	1	3	1	3	1	1
high income	0,9	3	1	3	3	1	1

Figure 8. model outputs. From (a) to (c), urban form corresponding to iterations 01, 11 and 31; from (d) to (f), the relative accessibility for the same iterations (Source: author simulation based on Saraiva).

From the target accessibility definition, one can verify its impact on the relative accessibility grid. To this end, the 11th iteration was selected, in which the difference between the *relative accessibility* and agents *target accessibility* was examined, as shown in Figure 9.

The results reveal the influence of the target accessibility parameter for the three agent types modeled. This measure is added to the weighing of the remaining model attributes, making the final interests matrix for each of the agents, as recorded in the Image 10.

Figure 9. Target accessibility weighing. a) relative accessibility for iteration 11; b) low income agents; c) average income agents; and d) high incomes agents.

Figure 10. weighting for all attributes; a) low-income agents; b) average-income agents; and c) high-income agents.

The creation of different bands among agents' preferences can be observed in the results. It shows the expected responsiveness and sensitivity of the agents' evaluation of the different environmental settings. In the same vein, in comparing the weights with the results of the growth model, it can be noted how the development pattern of the city may have different readings under these "disturbances" from the agents' points of view. The accessibility (a general system measure, even if locally generated) is then defined by a simple method through the particular accessibility feature, as can be seen in Figure 11.

Figure 11. comparisons between model results; a) relative accessibility grid (it.11, highlighting column 17); b) distribution of the column 17 results from the relative accessibility grid; c) low-income agent particular accessibility grid (it.11, highlighting column 17); d) distribution of the column 17 results from the particular accessibility grid.

The relative accessibility and particular accessibility grids comparison expressed in the Figure 11 helps to appraise the impact of this measure. The figures for both variables are shown in Figure 11b (relative accessibility) and Figure 11d (particular accessibility). In these, it can be

perceived that the approximation of the highest values to those areas closest to the agents preferences, such as those cells in which the relative accessibility is around 0.2.

Moreover, the differentiated spatial perception for the low-income agents has largely decreased their interest on the more central cells through the selection of a reference value for relative accessibility, as noted in the Figure 11c. It has also created plateaus of interest that span over the urban areas surroundings. The grid column 17 (shown in Figure 11d) presents interest peaks (around to 0,95) on lines 19 and 20, on those cells which are contiguous to areas which are already urbanized at that time (iteration 11). This pattern is prolonged in a collar shape all around the urban area and lies over cells which are not yet urban (in a prevalent manner at least, so as not to be given the urban cell type in Image 12), but have enough accessibility and will turn urban in the following iterations. This high interest dedicate to these cells coincides with the pioneering role that low-income present in peripheries (Barros 2004; Abramo 2012).

It should be pointed out that for the low-income agents there are large high-interest plateaus on the peripheries beyond the collar region (with values ranging from 0,80 to 0,94). If the modeler would not consider factors such as tenure, urban norms and so forth, these areas can be seen as high potential sites for low-income settlement. This could help explain the great adaptation capacity of low-income populations and their greater flexibility of location choices. If compared to high-income agents, the low-income ones have 28 times more location options (1.238 cells with $t_{\text{low-inc}} \geq 0,85$, versus 43 with $t_{\text{high-inc}} \geq 0,85$). Obviously, these low accessibility areas are lacking in urban infrastructure and are not urban for their greater part. If this were true, low-income agents would have more choices from the worst places (considering urbanization) while the high income would have fewer options on better locations. It seems clear how these relationships can generate conflicts over urban form and its benefits.

Figure 12. Composite from Quickbird image and agent concentration areas. Low-income agents in orange, average-income in green and high-income in blue.

The consideration of remaining attributes brings into view its links to the agents' profiles. Figure 12 shows the preferred areas for the three types of agents through the classification of

each agent's preference matrix (which stand alone in Image 10a, to low-income agents; 10b, to average-income, 10c for high income).

An inverse Chicago Model is then apparent: the high-income populations settle inside the urban areas and leave the peripheries to the lower-income populations. The outwards expansion tendency for low-income populations is also visible. This happens according to secondary (to the accessibility status) influences as the road network, watersheds and so forth (Bógus & Taschner 1999). Instead of presenting the prevailing economic motivations, these settlement patterns are disturbed by other motivations that actually restrict the final interest spatial pattern. For the low-income agents, the final pattern corresponds to 70% of the particular accessibility pattern (1,238 cells with $t_{\text{low-inc},Ap} \geq 0,85$, against 845 with $T_{\text{low-inc}} \geq 0,85$). Figure 13 shows the difference between the particular accessibility grid distribution and the interest matrix.

Figure 13. particular accessibility grid compared to interests matrix. a) Particular accessibility and interests matrix subtraction modulus for low-income agent (it.11, highlighting column 17); b) difference between the distributions of the results of column 17 from the particular accessibility grid and interest matrix for low-income agent.

Final remarks

With regard to the question posed for this implementation, the influence of individual decisions on land use patterns can be ascertained, including those associated with poverty. Even on simple weighting of preferences over the environment, it is observed that the inclusion of varying agents' characteristics results in adjusted preferences patterns that drive each agent to a specific cell group on the environment. This steering is sensitive to the attributes selection; the attributes' weights as well as to the attributes' base values, as is apparent in the model results.

Several important challenges remain to be overcome, such as the deeper investigation of the associations of urban attributes and agents; the strengthening of methodological basis for the model; the definition of the movement and allocation processes and the insertion of these features in the software framework.

Even with these limitations, the model displays initial viability for modeling morphological dynamics in interaction with explicit social processes. Regarding empirical questions on the topic of poverty areas on contemporary Brazilian cities, the current implementation has produced embryonic approach to criteria definition for each of the modeled agents. The

registered effects indicate further possibilities on the study of linkages between morphological characteristics, environmental and social agents' motivations. In this sense, the perceived adjustment in the agents' parameters sensitivity reinforces the need for calibration from a theoretical, empirical or even hypothetical basis.

The model also displays some initial progress regarding its theoretical assumptions. It may enable the advancement of decision-making systems grounded social and geographical bases. It seeks to bring urban growth models closer to social modeling tradition of Timmermans and Golledge (1990) and Epstein and Axtell (1996).

Similarly, the Uneven Development Theory (Harvey 1978; Walker 1978) may also be represented by urban growth based on weighted accessibility and the unequal settlement patterns produced for agents. The current experiment suggests that agent environment awareness, preferences and movement, once deployed, will allow the representation of formal and informal market dynamics through divergent preferences and conflicting behavior. The heterogeneity in their preferences, tolerance, power and information culminate in parametric (on their environment assessment) and strategic (as compared with other agents) rationalities (Abramo 2012).

Methodologically, it appears there is a suggested increase in capacity in the CityCell framework, with the addition of micro-specification (Epstein & Axtell 1996) of the attributes weights for each agent. One can then generate modeling hypotheses with greater clarity as to its theoretical and empirical assumptions and include the autonomous rationality principle.

On the issue of formation of poverty areas integrated with city growth, the hybrid approach of cellular automata and agent-based models can qualify investigations in urban models of morphological basis by increasing the specification of its dynamics and by allowing the contradiction between its social actors.

Urban street tree modelling using high-polygon 3D models with photometric daylight systems

Marcus White, Nano Langenheim

Faculty of Architecture, Building and Planning, The University of Melbourne, VIC 3010, Australia, E-mail: mrwhite@unimelb.edu.au, n.langenheim@unimelb.edu.au

Abstract. The choice of street tree species, size and placement is an integral part of street design in any city, but particularly in cities with large seasonal temperature variation such as those experienced in Melbourne, Australia. The arrangement and choice of street tree can make a street seem too dark in winter or not provide enough shade in summer. Trees have traditionally been difficult to model digitally and have been considered “polygon-heavy” (thousands of polygons) making them computationally prohibitive to use for three-dimensional modelling and rendering analysis, particularly on an urban design scale. Thus street tree assessment is typically limited to spreadsheet /database form, two-dimensional plans and sections or photographic collage to test aesthetic implications. In this paper we discuss methods which bring together developing research into mathematical algorithm tree simulation, increasing processing power in affordable personal computers along with improvements in render engines with photometric daylight analysis along with efficient ‘proxy objects’ which allow large numbers of highly detailed three-dimensional representations of trees to be rendered. We discuss the initial results of this study demonstrating that it is now feasible to use high quality three dimensional polygon street trees in urban models with photometric daylight analysis. We report that it is now possible to assess the solar amenity and shade impact of a variety of tree species at different seasonal and time intervals with an iterative design process allowing multiple scenarios to be tested effectively in short periods of time.

Key Words: Tree modelling, urban modelling, livability, urban forest

Introduction: the growing importance of street trees

Street trees can have a tremendous impact on the quality of public spaces relative to cost (Moore 2009) and the choice of street tree species, their arrangement and spacing is an integral part of street design in any city.

In cities with large seasonal temperature variation such as Melbourne, the arrangement and choice of street trees needs to be considered multi seasonally. Large dense evergreen trees might seem a good choice for the summer months when we are experiencing heat waves of 40 degrees Celsius for stretches of four or five days at a time (BOM 2013) but this choice might also make the street seem dark and oppressive in winter when the temperature is nine or ten degrees and overcast skies are common.

As a result of climate change, heat waves are likely to increase in frequency, intensity and duration (Akompab et al. 2013) and Australia is particularly susceptible with increasing extreme weather events (Patz et al. 2005). The micro climatic benefits of street trees in heat mitigation of urban environments (Oke 1988) are thus becoming increasingly important as is the need to be able to model these environmental impacts.

Maximizing the health and productivity of Urban Forests is becoming an accountable activity (McPherson et al. 2012). In cities facing great change such as Melbourne with its high number of trees nearing the end of their useful life expectancy councils will need to visually represent to the community why replacing ‘like with like’ (Shears 2009) will not always be appropriate. Without the community ‘buy in’ on trialing new more resilient and conditions specific trees the council may face heavy pressure to replant existing species regardless of the evidenced against it.

In this paper we provide the background of how street trees have traditionally been selected, how they have been modelled and discuss how recent advances in both software and hardware may potentially impact on how we model street trees in the future.

We go on to describe our method of bringing together important aspects of previous street tree modelling along with some of the new hardware and software such as parametric proxy object tree modelling with photometric daylight system modelling.

We test our new modelling approach on a case study area within Arden Macaulay are no the north of Melbourne, Australia and continue with a brief discussion and conclusion based on our findings.

Background: How street tree species have traditionally been selected

Preferred Species List

In the previous decade, when selecting tree species for streets, a designer would refer to the 'council preferred species lists'. The lists were based mainly on the civic image of that a shire or council: (Ely 2009) I.e. Moreland City Council, a suburb of Melbourne had a list with a high proportion of native and indigenous species (MCC n.d.) while the City of Melbourne list had a higher proportion of deciduous boulevard species (COM 1998).

How aesthetic values drive street design

In current practice, aesthetic values such as symmetry still play a greater role in street scape design than do ecosystem benefits; (Ely 2009) for example; larger trees on the north side of an east west street could be evergreen, providing shade for the road and footpath depending on their size and the street width. Traditionally street tree planting would be that the same species used on either side of the street but use of the same large evergreen species could overshadow the adjacent buildings on the south side of the street and make the street appear too dark in winter (Jim & Chen 2003).

How tree spacing can impact both the tree and the environment of the street.

The spacing between trees dramatically effects the qualities of the street environment. Spacing that is too close effects form, requiring trees to grow taller and narrower to compete for available light eventually leading to structural instability. Too far apart and the gaps between the canopies deplete the street scape legibility leaving an inhospitable low thermal comfort environment for cyclists and pedestrians during the summer months (Norton et al. 2013).

Trees as green infrastructure.

In recent years there has been a growing recognition of the ecosystem benefit trees provide in cities (Ely 2009; Young 2010). Their contributions include; mitigation of the Urban Heat Island Effect (Lindberg & Grimmond 2011), air temperature cooling through shade and evapotranspiration (Shashua-Bar et al. 2010), grey water filtration (Gómez-Baggethun & Barton 2013) pollution filtration (Maher 2013) noise attenuation, reduction of pedestrian UV exposure and thermal comfort (Parisi et al. 2000; Parisi et al. 2001). The understanding of urban trees as vital green infrastructure has led to large scale research projects which begin to quantify tree requirements for survival in complex urban environments (McPherson et al. 2012).

Tree model quality and why they are not currently used in precinct scale modelling

While it has been possible to model complex geometries such as trees, shrubs and grass with realistic results for over a decade there have been issues with balancing the level of realism with the speed of the model to regenerate or render for images that contain multiple complex objects. (Weber & Penn 1995) Even two or three polygon-heavy trees can slow down a model and make rendering times prohibitive. Precinct scale plans and perspectives may contain thousands of trees.

Modelling of precinct scale plans and perspectives is not popular as the realism of the trees is usually compromised through abstraction or reduction to minimum polygon 'billboards' (photographs of trees applied to flat polygon faces). Sometimes trees are left out altogether. (Radford et al. 1997)

Due to the difficulties of representing multiple trees in three dimensions, two-dimensional plans and sections; council 'preferred species' lists; and sometimes photographic collages are more commonly used than 3D models to discuss the role of street trees in the urban environment (COM 2012; COM 1998; DCC 2012; MCC n.d.). The result of this lack of three dimensional modelling means that the effects and requirements of trees have not been considered in an integrated manner (Ely 2009).

Current urban forest research is enabling more quantifiable strategic street tree selection. At the same time advances in computer software which calculates and replaces a mesh tree model with a 'proxy object' and hardware improvements, allow highly accurate tree models to be included in precinct scale digital models. This allows tree selections to be included in a rapid iterative design processes with enough accuracy to inform current urban design practice and assess some of the solar impacts of tree canopies over a trees lifetime / season.

2D tree modelling

In traditional planning documents, streets are represented in 2D cross sections and small portions of plan. These types of representation are primarily designed to show pavement and roadway widths, parking provision and building setbacks and are not really capable of expressing the quality of the street environment through the seasons or through the duration of the growth of the tree (Radford et al. 1997). In these drawings tree canopies are commonly represented at about two thirds of their ultimate size which they may take twenty years to attain. Canopies in plan are represented as a more or less a circle which hides some of the common pruning subtractions regularly made from urban trees to allow for building facades, power lines (Figure), tall vehicles such as buses and trucks, pedestrians and cyclists.

Figure 1. Photograph showing impact of pruning around power lines on Arden Street in North Melbourne.

The post-production ‘collage’ modelling

When 3D modelling is used, buildings and street widths are modeled and used to analyze spatial qualities and overshadowing but ‘post-production’ trees are commonly inserted as photographic montages as seen recently in the Swanston Street redevelopment scheme (Melbourne, 2009). This method can be visually compelling and can show reasonable tree shadows but the drawback is it’s intensively manual and inaccurate. To produce images of the street environment over the life time of a deciduous tree, good quality images of the tree in summer, winter and autumn are needed and at three stages of the trees life cycle, nominally five years, ten years and twenty years. Each tree in the montage is manually scaled to the perspective of the render and often scaled to the needs of the image composition rather than true dimensions of tree growth (3DArtistsonline 2007). This makes it an unsuitable method for rapid testing of different scenarios. It is used mainly for final presentation images after all decision making is completed.

2.5D tree modelling – GIS database modelling

In 2006 *Itree*TM was released by the USDA Forest Service. It is an open source, GIS database program and it allows for the creation an abstract model tree. This program has been used by the USDA Forest Service since 2005 to establish an accessible International tree growth database (McPherson et al. 2012) and by Melbourne City Council to catalogue and assess their urban forest. In the USDA case, complex urban growth parameters have been recorded for 17,000 existing tree specimens over 16 climatic regions over the last 10 years. The database can output a height over time predictive lollypop model for specific tree species under differing climatic, management and environmental conditions. This is groundbreaking for the management and selection of trees for the urban forest. The output is a very sophisticated data-rich abstract model, though does not assess complex three dimensional formal aspects of the trees.

3D low detail level tree models - ‘lollypop’ modelling

One method of modelling trees utilized by urban designers and others for a more detailed assessment of the environmental impacts of trees over time is commonly referred to as the lollypop tree or ball on a stick model (Voris et al. 1993). This is a very efficient modelling method which can be used for large scale planning but the drawback is that the visualization output is highly abstracted and cannot be used to assess 3D quantities of shade or aesthetic nuances between a deciduous or evergreen tree or represent individual tree species form.

The need for realistic visualizations to garner community support for tree species selection based on empirical evidence of that species long term ability to survive or thrive in highly specific climatic and environmental conditions is well recognized by urban designers and planners globally (Pettit et al. 2009; Shears 2009).

The production of visualization imagery for community consultation has been explored in a decoupled manner as real-time rendering has been considered computationally prohibitive (Grêt-Regamey et al. 2013). External databases or libraries of low-polygon landscape elements and vegetation which can be drag and dropped into a scene such as those developed for the Victorian Resources Online (Pettit et al. 2009) or as pre rendered urban design scenarios developed in a separate visualization software from given GIS database inputs have been explored in the past few years. These models use the GIS database for decision making and the 3D visualization as an advocacy tool (Grêt-Regamey et al. 2013).

Detailed 3D tree – high-polygon modelling

Tree and plant modelling has been developed for vastly differing purposes in a wide range of disciplines since the late 1960’s. In computational botany (Prusinkiewicz & Runions 2012;

Reffye et al. 1988) the aim of the model is high botanical accuracy. These models represent plants in realistic detail at close range but are often computationally heavy. In computer science the aim of the model has been to capture morphological aspects of plants in the most computationally efficient manner allowing for degradation of the model according to the distance that the plant is from the viewer ultimately aiming for realistic looking vegetation for real-time rendering in flight simulators, gaming and other virtual outdoor environments (Rebollo et al. 2006).

Trees are broadly modelled in three ways: Rule based / procedural models the most well-known of which is L-systems developed in 1968 by Aristid Lindenmayer and Przemyslaw Prusinkiewicz (Lindenmayer 1968; Prusinkiewicz et al. 1990); Image based models using photographs of existing trees either mapped onto billboards or a partially image based canopy mapped over a modelled trunk and branches (Neubert et al. 2007) and more recently; Sketch based models for touch screens (Longay et al. 2012). Many programs hybridize between the three approaches. The focus of each program is different ranging from high botanical accuracy, (Reffye et al. 1988) though to efficient polygon counts (Pettit et al. 2009), to user type (botanist or non-botanist), user edit ability and speed of model creation (Ganster & Klein 2008).

For our purpose we need a balance of both adequate botanically accuracy whilst being efficient enough to render in reasonable time frames.

Improvements in hardware and software

Processing power in personal computers

Processing power and graphics cards have substantially improved in the past fifteen years in affordable personal computers. In 1998, a high end computer used for modelling and rendering may have been a 400Mhz P2 64mb sdram running at 100 mhz with one or two voodoo 2 cards (90mhz core). The rendering for this paper has been produced on a 2013 laptop with an Intel Haswell 4 i7-4940MX 3.10GHz 32GB 1600MHZ DDR3 Memory NVIDIA GeForce Go GTX 880M 8GB. This simple comparison illustrates the incredible advances in personal computers (the ram alone is 500 times greater) and according to Moore's law (Schaller 1997), is an indication of what we should expect in the near future. Modelling with thousands or even millions of polygons is becoming possible.

Parametric proxy object modelling

In addition to improvements in algorithms which degrade the 'level of detail' of tree foliage according to the viewer distance from the object (Rebollo et al. 2006), there have been great advances in software that takes advantage of processor and graphics card hardware improvements by storing the geometry in the main memory or in the graphics card itself (Rebollo et al. 2007). The graphics card can store one render of the modeled tree and use algorithms to calculate the rest of the 'proxy objects' based on that first tree.

'Proxy object' modelling is now commonly available within architecture and animation industry software such as Autodesk's Maya™ and 3ds Max™. Taking full advantage of this modelling method is a parametric tree placement plugin by ITOO software™. This plugin allows thousands of trees to be included in a scene before the model begins to slow down prohibitively. Tree placement is managed through the plugin either by map, region or polyline meaning that the tree model species or growth stage can be replaced parametrically across the precinct in rapid succession. Spacing can also be set to 'self-adjust' by changing the object 'collision' settings. Manual tree placement in models of this scale would take days to adjust for a change in species in particular the change in spacing with many of the previous modelling methods discussed.

Render engines with photometric daylight analysis

Also now common animation software such as 3dsMax™, are the algorithms for daylight rendering which have been improved with photographic quality rendering possible (O'Connor 2010). There have also been advancements in light modelling for energy rating requirements such as 'Green Star' or 'LEED' rating (Reinhart & Breton 2009). It is now possible to calculate a grid of lux levels in a digital model based on daylight expected at a given time of day, for a given day of the year that takes into account direct sunlight, indirect ambient light from the sky and reflected light from surrounding buildings. These light meter grids are designed for internal use (to assess task lighting etc.) but here we are using them externally to assess light and shade levels of streets.

The software also allows control over the model to output the shade cast by the tree even though the tree model is turned off or rendered 'non visible'. The render output allows the shade of the tree(s) to be assessed without the obstruction of the canopy or structure of the tree itself (Figure) and data grid exported for further analysis in spread sheet form (Figure).

Figure 2. Rendered plan view of tree showing lux meter grid. LHS showing top of canopy, RHS showing the tree 'hidden' but still casting shadows.

Figure 3. Lux meter grid exported to MS Excel for further analysis.

The aim

The aim of this paper is to demonstrate a new, rapid, integrated approach for precinct scaled streetscape modelling with highly detailed 3D trees. The approach is aimed at providing landscape architects and urban designers a swift method for quantitative solar/shade impact assessment; visual assessment; impact of tree development over time; impact of species selection; spacing; and positioning so that street trees are a more integral part of the street design process resulting in higher quality, resilient and more comfortable urban spaces.

Method

In this paper we discuss a new approach to street tree modelling which bring together developments in highly detailed and botanically-accurate algorithm tree modelling; increasing processing power in affordable personal computers; improvements in render engines with

photometric daylight analysis; and efficient parametric ‘proxy objects’ which allow large numbers of highly detailed three-dimensional representations of trees to be rendered.

We demonstrate this new approach to street tree modelling with a simple case study – modelling a precinct within Arden Macaulay a suburb within the City of Melbourne.

Case study application: Arden Macaulay

Arden Macaulay – an area of future change

Arden Macaulay is a precinct within the City of Melbourne which will be rezoned from industrial use to residential. By 2030 this precinct, which currently houses two to three thousand people is expected to house twenty five thousand (COM n.d.). The structure of the precinct will undergo great change from predominantly low rise one and two story buildings to multi story buildings between four and ten stories high putting pressure on public open space amenity. The green infrastructure of this precinct will be provided predominantly on the streets and the council is currently formulating a 40% canopy coverage strategy which means that this particular renewal area is set for dramatic change.

Applying the high-polygon parametric ‘proxy object’ and daylight assessment approach

The modelling shown here is our first test of this rapid high polygon parametric proxy object and daylight assessment approach applied on this precinct of Melbourne.

We built a simple 3D model of the precinct using a mix of the council’s cadastral data, Lidar contour data and 3D textured buildings using Google Building Maker™.

The individual tree models we used for this test combined the empirical modelling techniques of L-systems with parameter based controls (Lintermann & Deussen 1999). The tree models combine high level botanical detail and potentially photo-realistic material qualities and high quality shadows, the accurate of which is the topic of concurrent ongoing research.

The parametric L-system trees were converted proxy objects and then parametrically arrayed along footpaths so as to allow rapid adjustment of tree spacing or tree size and species. A variety of tree species were tested as well as different spacing’s and different times of the year.

Figure 4. Aerial rendered view of Arden Macaulay area showing planting of: *Corymbia maculata*.

Figure 5. Aerial rendered view of Arden Macaulay area showing planting of: - *Corymbia maculata*, 20m spacing.

Figure 6. Aerial rendered view of Arden Macaulay area showing planting of *Corymbia maculata* 7m spacing. Summer.

Figure 7. Aerial rendered view of Arden Macaulay area showing planting of *Platanus orientalis* 7m spacing, Summer.

Figure 8. Aerial rendered view of Arden Macaulay area showing planting of *Platanus orientalis*, 7m spacing, Winter.

Figure 9. Aerial rendered view of Arden Macaulay area showing planting of *Platanus orientalis*, 20m spacing, Autumn.

Figure 10. Aerial rendered view of Arden Macaulay area showing planting of *Platanus orientalis*, 20m spacing, Summer.

Figure 11. Aerial rendered view of Arden Macaulay area showing planting of *Platanus orientalis*, 20m spacing, Winter.

As the model was parametric, simple parameters were able to be adjusted and the model would update immediately. To change the species of tree was just a matter of clicking to substitute the original high-poly tree model with another.

A lux meter grid was also set up to measure light levels on the street and footpath, with readings taken for each of the different scenarios. The lux meter grid was calculated with a few seconds and was exported to Microsoft Excel via a .CSV exchange file for further processing which allowed qualitative comparisons of the data.

Figure 12. Aerial view of lux meter analysis of the Arden Macaulay area of Melbourne assessing light levels of the street taking into account tree shade and light reflected from building forms for 4pm 21st of June.

Figure 13. Plan view of lux meter analysis set to higher resolution for the Arden Macaulay area of Melbourne assessing light levels of the street taking into account tree shade and light reflected from building forms for 4pm 21st of June.

Discussion and conclusion

This method allows for several thousand trees to be included in a scene without making the model untenably slow to regenerate or render. The models are accurate enough to measure canopy projections under zenith angle when rendered with the photometric sun producing realistic images of quantities and qualities of shade in urban design scale projects. In this study we were only looking at shade and accurate iterative visualization but there is scope to develop the method to output eco-system benefit, micro climate and thermal comfort mapping.

Future research is required to ascertain if the models can be calibrated accurately enough to output other predictive measurements such as leaf area index, leaf area volume and rates of evapotranspiration of urban trees in specific microclimatic and spatial conditions such as pruned for power lines, facades, footpaths and road clearances, low light availability and constricted soil quantities.

This new approach to modelling street trees could potentially be used by urban designers and landscape architects working with Councils to supplement GIS/database decision making, allowing solar impact and visual assessment alongside other less three dimensional aspects of tree data.

Being able to present change involving trees in an iterative manner which expresses their visual and shade impact in very realistic terms may be beneficial to the study of urban forestry and presentation of the strategic decisions it makes possible and potentially be a powerful advocacy tool.

Our research allows further analysis of the impact of large scale tree planting or replacements. It makes a contribution to an iterative street design process where multiple scenarios and multiple species can be tested and assessed quickly at different stages of growth with a reasonable level of accuracy, using detailed three-dimensional representations of trees at various growth stages in a spatial environment which provides accurate sun positioning and therefore shade qualities through its photometric daylight system. This method raises potential further investigation of the three dimensional street qualities with the additional dimension of time – looking at how the movement of the sun over different times of the day and different angles throughout the year might influence the design of north-south or east-west streets.

Our initial results of using this new approach to street tree modelling demonstrate that it is now feasible to use high quality three dimensional polygon street trees in urban models with photometric daylight analysis. We are now able to assess the solar amenity and shade impact of a variety of tree species at different seasonal and time intervals with an iterative design process allowing multiple scenarios to be tested effectively in short periods of time.

The recomposition of urban public spaces. Case study of the historic centre of Noale, Italy

Enrico Pietrogrande, Alessandro Dalla Caneva

Department of Civil, Environmental and Architectural Engineering, University of Padua, 35131 Padua, via Marzolo 9, Italy.

E-mails: enrico.pietrogrande@unipd.it, alessandro.dallacaneva@unipd.it.

Abstract. *The theme of this paper is the recomposition of public spaces in the ancient town when compromised by old and recent speculative interventions. The working method is based on the belief that, in the study of urban morphology, is basic to analyse the history of the city, clarifying the relationship between permanent structures on the one hand and temporary ones on the other. The history becomes an indispensable tool to know the deep reasons of the urban structure which is the memory and the image of the community. The paper is based on fundamental 1960s studies and following about typological analysis (Aldo Rossi, 1966; Carlos Martí Arís, 1993) specifically oriented towards the theme of public spaces. The spatial aspects and formal image of the transformations in the city are studied as a premise for the design of the new architecture. Noale, not far from Venice, was one of the subjects the students on the course of Architectural and Urban Composition 2 at the Department of Civil, Environmental and Architectural Engineering of the University of Padua specifically investigated as an opportunity to redesign the unity of the historic centre of this town that had previously been lost.*

Key Words: Memory, history as a tool for the project, public space, city centre

Introduction

The town of Noale, which has about sixteen thousand inhabitants, is situated at an equal distance from Venice, Padua and Treviso. The centre of the town is crossed by the busy regional road No. 515 Noalese, in a rural area that is completely flat and marked by the remains of the Roman 'graticolato' grid system, a checkerboard of land division that goes back to the time of ancient Rome. The ruins of the medieval castle and the course of the Marzenego river enrich the site of the city.

A lively centre as far as social and economic life are concerned, Noale still has some unresolved issues in the relationship with the wider urban area that bears witness to its rich past. The city in fact shows aspects of pronounced inconsistency related to random and disproportionate architectural constructions built in successive periods of the last century, and heavy car traffic. In particular, it seems disorganized in the form of the fabric of the area today called Largo San Giorgio, located east of piazza XX Settembre, the centre of nineteenth century Noale. This paper concentrates on the Largo San Giorgio area, and also considers some nearby areas of the historic city.

With our students on the course of Architectural and Urban Composition 2 at the University of Padua (regular professor Enrico Pietrogrande, coworkers Adriano Rabacchin and Alessandro Dalla Caneva, academic year of 2012-13), we studied new architectural proposals to recompose the unresolved condition of the Largo San Giorgio area based on analyzing the history of the village to understand its urban morphology. This is an indispensable tool in discovering the underlying reasons for the development of the urban structure, which forms an indelible reminder made in the image of the community. Fortunately, enough traces of the previous physical reality remain for understanding the morphology that underpinned the urban evolution to be recognized and read. Students were required to modify the existing buildings whenever they are in conflict with the surroundings. This request assumes that history is an instrument in opposition to the museumification of the historic city and in favor of its transformation since in

terms of structural features it accepts the insertion of new buildings in the historic urban fabric on condition that these are planned by studying the pre-existing organization of the space, the construction system, and the urban relationships of the buildings with the environment from a planning point of view.

Figure 1. The ruins of the Tempesta family castle in Noale. Picture taken at the beginning of the last century.

The idea that the transformation and the protection of the urban landscape can occur according to a unitary process is the basis of the teaching experience described below. The assumption is in line with the main contribution of the most advanced teachers in Italy on this subject at the University Institute of Architecture in Venice during the second half of the twentieth century, the so-called School of Venice. According to them, the relationship between a city and architecture, referring to the city's scale in the study of architecture, is the fundamental fact that is at the origin of an effective theory on the project, which defines a synthesis between analysis and design, architecture and urban planning. Aldo Rossi was an architect and a teacher particularly relevant in the School of Venice. He insisted on the absolute consistency between the analysis of building and urban analysis, emphasizing the importance of finding precise relationship between architectural and urban structures (Rossi, 1970). His fundamental 1960s studies about typological analysis, specifically oriented towards the theme of public spaces, were published in 1966 in the book *L'architettura della città* (Rossi, 1966), in which the spatial aspects and formal image of the transformations in the city are studied as a premise on which to base the design of the new architecture.

In the teaching experience presented in this paper the first phase of the project the students had to elaborate was composed of analyzing the land registry survey map and written, pictorial, photographic records, in order to acquire informations about the past of the city centre and study the relationship between architecture and urban structure.

Context

The development of Noale, village of late Roman origins, occurred during the medieval period in conjunction with the construction of the castle of the Tempesta family (Figure 1) and the fortification of the village. The castle and the fortified village, surrounded by ditches fed by water from the Marzenego river, constitute the core (even today easily identifiable) around which the city expanded (Figures 2 and 3).

The area on which students focused attention extends east of the ancient village, at the convergence of roads coming from the towns of Mestre and Mirano that originated in the encounter point piazza XX settembre, the 19th century Noale centre. Here a new space took shape, that is today without order in the arrangement of buildings. This space, that stands at the

east limit of piazza XX settembre, is named Largo di San Giorgio (Figure 4).

Figure 2. Noale: planivolumetric representation of the current condition. The area is cut vertically in two parts by the regional road No. 515 Noalese. The old castle and what remains of the ancient fortified village are to the left, while to the right is possible to see the town later developed with the triangular piazza XX settembre and the two convergent roads from Mestre and Mirano. From the work of the student Silvia Tarallo.

The dedication to San Giorgio derives from the name of the church and the hospital which stood in the area already by the second half of 13th century and were complemented by a convent at the beginning of the following century. In the early years of the 15th century the church and the hospital were demolished and rebuilt with larger size, the church where previously insisted with the façade on the current piazza XX settembre (Figure 5) and the hospital on the other side of the road to Mestre. The convent, behind the church, was enlarged a few years later and housed until 1769 the Minor friars religious order.

Then, after the expulsion of the friars, the landlord Diodato Bembo purchased the property and proceeded to recast the church eliminating some parts (such as the sacristy, the bell tower and the additional nave) and to build in 1770 palazzo Bembo (Figures 6 and 7), a “building with portico that delimits even today the piazza XX settembre on the east side” (Dal Maistro, 1994). In the same period boundaries with the road to Mestre were also modified and the convent was demolished.

From that moment, the church of San Giorgio lost importance, until in the last years of the 19th century it was demolished too. In subsequent years, the area did not undergo further revisions as regards the boundary on piazza XX settembre while on the back, to delimit the part that we call Largo San Giorgio and which constitutes the project area in the workshop conducted with the students, two buildings aligned on the road to Mestre were constructed, a covered market (Loggia del mercato) in 1930 near palazzo Bembo, and an imposing building designed to accommodate a bank in 1910.

Figure 3. Noale: growth of town from the 11th century to nowadays. From the work of the student Silvia Tarallo.

Current problems

The area of intervention today has very special connotations. Piazza XX settembre continues to be in fact a node of fundamental traffic as the place of intersection of the roads to Mestre, Mirano, Padova and Treviso (Figure 8). It isn't managed as a square, but rather as a parking lot, and for the characteristics of the traffic that has got, this place has become a roundabout road.

To the state of decay of the piazza is to sum up a veritable state of degradation of the specific area of intervention, largo San Giorgio. Here, near the mansion built by Bembo on the square in 1770, the bank and to the Loggia del mercato, have arisen from many years, so random and disordered, a new housing block, several garages, a two storey house with run-down aspect and other incoherent volumes.

Figure 4. Piazza XX settembre, planivolumetric plan of the current state. The Largo San Giorgio area is located east of the piazza, delimited by the piazza itself, the road to Mestre (north side), the road to Mirano (south side). From the work of the student Silvia Tarallo.

Largo San Giorgio has therefore today the following negative characteristics. First of all, the discontinuity of the volumes on the front of the road to Mestre, culminating in a empty space, which is also a parking lot, at the point where the road originates from the square. Then the neglect of the area behind the building of the bank, a garden not cared and unused. Finally, the low quality of the façade on largo San Giorgio of the new residential building which has the main front located along the road to Mirano.

It's then necessary to dedicate a reflection to the viability of the zone, with regard to the system of the car parks and the traffic of cars and bicycles. In the area there are many car parks: the road to Mestre has parking on both sides, the piazza XX settembre is used as a car park, largo S. Giorgio and the area behind the Loggia del mercato have also the same function.

About the road system it's then interesting to observe the management that is set in such a way that piazza XX settembre is actually a roundabout with a single access road, the connecting

road between Noale and Mirano, and a single track of output, the connecting road between Noale and Mestre. The road that leads into piazza XX settembre at the western boundary of this is instead only accessible from the residents.

The complex system of automobile roads is accompanied by a system of partial bike paths that passes through the piazza. It is important to emphasize that the study of the organisation of the roads of the area has been amended several times recently and that it's still intention of the Public Administration of Noale to find a definitive solution different from the current.

The didactic experience

Two of the four projects presented here refer directly to the object of the study, the Largo San Giorgio area. The project proposals from students that put the stress on this area originate from the same premise, that is considered unavoidable: the premise that the area could be redeveloped with the demolition of the incongruous constructions, finding solutions that are conscious of the character of the place and that are able to pursue, in the intentions, a formal recognition of the place as being progressively lost within the community.

Figure 5. The church of San Giorgio in 1890, a few years before the demolition.

The issue of formal recognition refers to the possibility for people to belong to the place where they live through a process of symbolization of form. In fact, as stated by Cristhian Norberg-Schultz “the term ‘establish’ does not indicate a purely economic term, but an existential concept, which denotes the ability to symbolize meanings. When the artificial environment is significant, the man feels at home” (Norberg-Schultz, 1979). In this sense, the proposed projects represented a rather ambitious attempt to attend, in the project design, to the formal features of the tradition of Noale to rediscover and renew continuity with the historical memory of the community. The simple shapes that students often refer to in the project have this aim. The possibility is that these will be recognized by the people collectively, thus recalling a civil dimension of architecture in which a community recognizes its being in the world.

“I therefore support a civil dimension of architecture”, Malacarne wrote, “in which urban and architectural forms are the reflection of a collective experience that can minimise the individual aspect of the works by subjecting the form to an idea intended to be intelligible and even shared” (Malacarne, 2008).

Therefore, the project is part of the dialectic of the historical process in which preserving and building are components of the same act of consciousness. It is thus passed the irremediable antagonism between conservatives and innovators because the restore has to be understood in the sense of a re-enactment of the past and the building activity as a continuation of the historical process. In this regard Ernesto Nathan Rogers explains: “Many, who think to be innovators, have in common with so-called conservatives the wrong that both have deep-rooted prejudices, thinking that new and old are in opposition instead of representing the

dialectic continuity of the historical process. One and the other don't go beyond the veneration for certain fruitless appearances. They are not able to penetrate the essences of the styles, pregnant with inexhaustible energy. To try to a priori build in a modern style it is equally absurd to impose respect for the taboo of past styles" (Rogers, 1958).

Figure 6. View of the Bembo palace, built in 1770 aside the church of San Giorgio (1950).

Figure 7. Piazza XX settembre, with the Bembo palace to the right. The church of San Giorgio stood in the empty space aside the palace. Picture taken in 1960.

The first project of the student Valeria Gallana (Figures 9, 10 and 11) starts from the assumption of attributing to largo San Giorgio a public dimension. Gallana imagines to structure the empty space derived from demolished volumes through the narrative sequence of courtyards that reinterpret the idea of the Noale courtyard, inside which, in two of the four cases, a cylindrical volume refers to the typological idea of a building with a central plan. Therefore the court, as a formal feature belonging to the town of Noale, becomes the pretext for the invention of the design. The narrative sequence begins exactly where the demolished church of San Giorgio once stood, a space now turned into a court by walls of separation that found a link with the ancient wall with arches, which is all that remains of the vanished church. The court presents in the internal organization the same plan of the church reinterpreted as an outdoor garden. In a non-random way, another garden is located in the hollow cylinder at the conclusion of the narrative staged by the student.

The four courts each with a specific role have different hierarchies. The principal court to which the smaller ones are related has a close relationship with the Loggia del mercato that becomes the pivot around which the entire composition is disposed. The minor courts set out on an axis arranged to skirt the main public space are occupied inside by a building which, as

already stated, refers clearly to the idea of a central plan: cylinders that house within them, respectively, an exhibition hall and a secret garden for temporary sculptural exhibitions. The two cylindrical volumes are related to each other by a portico with two levels that mimics the classic idea of the *stoà*. Its presence is essential for at least three reasons. Firstly, to play the role of a system of relations between the cylindrical buildings; secondly, to separate the main space of the square from the private space giving access to existing residential buildings, thereby establishing an appropriate relationship between public and private space; and thirdly, to make a backstage area for the main square. The rhythmic pattern of the portico provides a principle of decorum to the square itself.

Figure 8. Noale, aerial view from the east. You can see the two roads, coming from Mestre (to the right) and Mirano (to the left) convergent to the piazza XX settembre.

The second project of the student Silvia Tarallo (Figures 12, 13 and 14) aims to redevelop the area through the achievement of a new market square. The square is exactly arranged in close relationship with the Loggia del mercato, the real pivot of the whole composition built during the Fascist period. The new square increases the value of the important pre-existences of the area as the cube-shaped building by classical form placed on the west and the same Loggia del mercato.

The module that marks the rhythm of the arcade of the Loggia del mercato is an opportunity to define a geometric trace on which the other volumes of project lie according to the well-known principle of unity in diversity: the tower and the public library.

The modularity of the geometric grid is achieved not only on the horizontal but also on the vertical plane, knowing that the geometry is only a means and not a goal through which you can pursue the aesthetic idea.

On the rhythm identified by the square module, the arcade with double height marks the square on the south. It's understood as a *promenade architecturale* that links the tower to the public library. The whole board of the pavement is related with the same grid. The identity of the library is here achieved through the arrangement of a body on the top that, mentioning the form of a classical temple, would metaphorically alluding to the sacred value of the library as a place custodian of knowledge.

The student put special effort to make clear the nature of the library of which appeared important to make clear not so much its way of functioning, but rather the representation of its value. Partly this explains the design process of the student who wanted first of all to think to the image that the library must have got and only later the way in which it must functioning, according to the assertion still considered valid of Étienne Louis Boullée for which the architecture is not the art of building and "we must first conceive and then we can build. The ancients built their huts only after having conceived the image (...). The art of building is therefore only a secondary art that we can define the scientific part of the architecture" (Boullée, 1780-1795).

Aldo Rossi who based the study of the city on its shape – “I always refer to the shape and architecture of the city, not its institutions” – came to the conclusion that the identity (of the form) depends mainly on the form itself, rather than on reason of a functional nature or, more generally, on political, social and economic values. This is especially clear in the direct words of Aldo Rossi, who, for example, expresses his opinion in these terms about the Palazzo della Ragione in Padova: “When you visit a monument of this kind, one is struck by a series of issues that are now intimately linked. Above all, one is struck by the plurality of functions that a building of this type can hold, functions that are quite independent of its form. It is this form that remains clearly imprinted in our mind, which we live and perceive and that, in turn, structures the city” (Rossi, 1970).

Figure 9. Project for the requalification of the Largo San Giorgio area in Noale proposed by the student Valeria Gallana. Ground floor plan.

The arrangement of the portico-loggia, as in the case of the project presented by the student Valeria Gallana, has the function of cleanly separating the public space of the square from the private space for access to the residences on the northern face of the square.

The city's tower, besides suggesting the presence of the lost tower of the church of San Giorgio, is a memory of the towers that make recognizable the secular square and the religious look of the figurative tradition that is found in Italy and beyond.

The scope of intervention chosen by the student Giacomo Orlandini (Figures 15, 16 and 17) regards a focal point of the historical residential buildings of the city of Noale, immediately behind the historic piazza XX Settembre. It corresponds to the long path that is perpendicular to the north front of the triangular square and connects this one with outlying parking space in the Piazza della Bastia at the point where the city meets the historic expansion of the twentieth century, recently completed to extend into the countryside. Piazza della Bastia has a close relationship with the railway station.

The choice to act on that connection axis originates from an unavoidable premise, namely that of redeveloping a historic pedestrian path, now Via De Gasperi, which has over time gradually assumed an increasingly important role in the system of relationships of the city. In fact, historical analysis has shown how a secondary path has with the advent of modernity become a privileged axis joining the historic centre and the train station. It was once a lane leading into the country through the private gardens of the Soranzo family, owners of the eponymous palace that now houses the public library.

Figure 10. Project planivolumetric plan proposed by the student Valeria Gallana.

The project aims to enhance the pre-existing environmental and historical conditions, tailoring them to the needs of the contemporary world, finding a formal relationship with the existing logic based on the paratactic arrangement and alignment of the long, narrow lot of medieval origin. The project is expected to recover, complete where possible, and extend what remains of rural housing, partly demolished during the World War Second, of which only traces remain in the sediment, arranged laterally along the connection path in long and narrow segments. The planned extension of the path is an opportunity to organize the volumes of the project around a courtyard, making a public space to pause along the way, but without invalidating the disposition of the parts according to the type of block built in depth. The proposed continuity with history, found through the use of a building material like the brick typical of the Venetian tradition, is accompanied by the will to respond to the demands of the community. In this sense, the project is intended as a cultural hub characterized by the presence of a museum and a public library to complete the existing library of Palazzo Soranzo. These buildings have their own individuality, each with its own recognizable form. The student's desire has been not to connect the entrances directly to the courtyard, but to intermediate spaces under the open sky and with an intimate character, echoing the medieval idea of secret gardens, where the controlled presence of trees and water suggest and demonstrate the picturesque character of the space, that belongs to the figurative tradition of the Middle Ages. This being a predominantly mediaeval environment, it seemed appropriate to stress the picturesque atmosphere of the place through a careful composition of asymmetries and misalignments, both in the plan and in elevation, rather than the symmetries that suggest a research mode of monumental effect, this not being considered suitable to achieve a formal mimesis with the existing environment. Rounding out the idea of an *ortus conclusus*, the volumes of the project are contained within the existing side walls, ancient elements of separation of property. These walls are reclassified and shown as elements of separation through a discontinuity with the buildings of the project, obtaining a functional gap in the perimeter circle of the water, an element that characterizes the atmosphere and history of the town of Noale.

The area of intervention chosen by the student Diego Bonaldo (Figures 18, 19 and 20) is located near the castle. Located in a space with an irregular trapezoid shape, it is defined by the presence of two permanent features: the environmental one of the Marzenego river and the artificial one represented by the axis of the main road linking Padua to Treviso. The area is located within a broader historical residential zone of support for the industrial district, built in the Second World War, which marks the limit of the partition between the historic city and the city of the new expansion. Historical analysis has shown that this area has remained over the centuries an empty space, only characterized by the presence of temporary wood buildings during the sixteenth century, defined by the presence of a residential building in the Napoleonic period, in line with the road leading to the territory beyond the city limits.

Figure 11. Views of the solution proposed by the student Valeria Gallana.

Figure 12. Project planivolumetric plan of the Largo San Giorgio area proposed by the student Silvia Tarallo.

The student decided, through more general morphological analysis of the city, from which he identified the particular character in the formal arrangement in depth of residential lots at right angles to the main road, to think of the project as a theoretical opportunity to revive the residential settlement in an existing line according to the type of the Gothic lot - long, narrow and perpendicular to the road, thus finding an analogy for and continuity with the historic city. The existing residential buildings are not changed in their appearance, so as not to lose the historical memory of the urban façades; however, the internal layout of the accommodation is redesigned, in keeping with the standards of quality of modern life, while a new element is the fragmentation of the property with external partition walls opposite the main facade, interpreted in the logic of the lot built in depth. The student was given the opportunity to rethink the two existing buildings facing north, the result of a late addition that is inconsistent with the existing buildings, through the provision of two volumes closing the northern front, a library and a small

exhibition space that meet the expectations of the community. The position of the two volumes plays a strategic role in terms of the urban view, becoming the fulcrum around which the public life of the residential district revolves. By virtue of this, the student decided to propose urban forms in an easily understood and recognizable form, directly linked to the history of the forms of historical tradition: the cuboid and the cylinder. The first contains the library, the second the exhibition space. This clear typological reference to buildings with a central plan of classical tradition and beyond becomes in particular an urban sign capable of interacting with its surroundings through its cylindrical shape and vertical rise, making it visible from a distance. The use of simple shapes stems from the belief that the specificity of architecture is to be attributed to the ability to produce typical forms, of general and popular impact, able to represent the collective memory: "I believed and still believe that if monuments are to be meaningful, they must not be difficult to understand. Therefore they should make contact with common awareness using patterns or stereotypes proper to the figurative universe of the masses and of all people together: they must belong to the common consciousness" (Polesello, 2003).

One last sign is placed to complete the composition. The presence of a high wall, pierced towards the castle, that follows the topographic trend of the site, designed to protect residential life, separating it from the existing public path which follows the course of the Marzanego river.

Figure 15. From the work of the student Giacomo Orlandini. Planning solution of the footpath from the new car park to piazza XX settembre and Largo San Giorgio, planivolumetric plan.

Conclusions

The study of the relationship between architecture and culture of the city lies at the heart of the above displayed planning hypotheses. In-depth study of the history of Noale is an instrument that clarifies the main aspects and opportunities. In particular, the research into the transformations of the spaces and shapes developing through time represented an indispensable premise for checking the planning proposal that aimed at reconstituting a coherent urban fabric in which residential and touristic uses play a role in connecting the distinct monumental phenomena present.

The investigation of the history of the city formed the basis of the project solution illustrated above, in harmony with the belief that in teaching it is essential to promote a synthesis between knowing and doing. The study of what is already present in the area and the broader historical-building framework is an essential tool in the promotion of a new cultural layout based on the needs of the area.

The future image of Noale also depends on the choices that will be made about the old city. The search for a formal reordering is motivated by the conviction that architecture is a fundamental means for promoting a new cultural and social asset in the areas investigated, where the new architecture draws inspiration from the needs of the territory. The on-going teaching experience at the University of Padova has also proved to be effective in making the relationship between lecturers and students a cohesive one.

Landscape design methods for surrounding mountain tops Yama-ate in Murakami Castle Town. *A test of GIS analysis*

Keisuke Sugano, Shigeru Satoh
Waseda University, Japan.
keisukesugano@gmail.com

Abstract. *The crowned mountaintops of Japanese castle towns are visible from the streets. This landscape composition is also common in East Asia, for worshipping Nature – a landscape design worthy of consideration. Although landscaping phenomenon can be verified via large-scaled maps, for specific aims, worship for example, it must be processed with scientific accuracy. Thus, this paper concerns itself with the relation between mountaintops and street centrelines; typological location accuracy needs GIS and GPS. With the numerical data from types of Object Roads, the Murakami Yama-ate shows three characters: i) its Object Road as framework, it holds a specific Vision Axis, ii) its periphery roads get twisted, so the Axis is adjusted to face Mountaintop, and iii) its Axis slides sharply; the appearance of Mountaintop becomes vaguely unpredictable. This research, concerning the Yama-ate Object Mountains numerically, believes in, also, the necessity to make these Mountains manifest from their histories, poetically; four points yielded, i) the Water God Animism in Miomote River, ii) Compass Direction, iii) Location and Boundary seen from the sea, and iv) Distribution of Ancient tombs and Castle. These four points are relevant to Murakami Mountains; historical and religious aspects are inseparable from their life on a day-to-day base.*

Key Words: Landscape design method, Sacred Mountain, castle town; GIS; Yama-ate.

Introduction

Research background and purpose

Basing on the Japanese aesthetic sense, the urban compositions of castle town are distinguished for their formative Arts of landscape, for the nature features and climates; topography and geological features were all respected and adopted in structuring urban design thinking. The main street of each castle town, built perpendicularly to the castle-crowned mountain, provides the pedestrian “Yama-ate” – facing the mountain castle view – including Shinto Shrine, Buddhist Temple and the Turret of Castle along the landscape axis. Renovating river for flood control, drawing river water for town use and so on was well planned. The town dividing and urban planning were done with religious respects to the sacred mountains and castle foundation banding with Nature.

Such urban composition was verified and common in Japan and other countries in the East Asian Continent, banding their life to surrounding mountains, paying respects, religiously, to Nature and perhaps even animism – a landscape design thinking with ecological wisdom and order, a way of urban construction working hand in hand with local culture – the ancient methodology worthy of consideration.

This research team, whilst intending to reveal the actual conditions of Yama-ate in bibliography 1) & 2), 3), has acquired the knowledge, by and large, of most castle towns and the adjacent cities in Japan. And so, this team is strongly conscious of designing the Mountain View enflaming the castle-crowned scene in particular, and those natural phenomena that are irrelevant to Yama-ate are roughly divided (from this research). Hitherto, this team consciousness is so far a hypothesis, and the designing intention of Yama-ate, planning and methods, are not yet verified.

This research employ the precise measuring capability of GIS, seeking to discover the *then* actual designing process of castle town from researching the landscaping of Yama-ate by means of GIS data examining. Then, studying these collected numerical data to reveal the characteristics of object roads, of the local culture associated with mountains, of documentary literature (about animism phenomenon for instance) and so on and so forth, this research concerns itself with the actual condition and wish to let the actual situation of the then castle town motivated Yama-ate design become manifest.

Research methods

This research starts on from making the data map for analyzing Yama-ate by GIS. The research team, to begin with, adopts the “2500 Base Information Map” issued by the Geospatial Information Authority of Japan and makes the Base Map of Murakami City; bettering up the map by using the geometry compensation tool of ArcGIS, and piling this map upon the historical map, this methods, piling and making a two-fold maps, reflecting the past and modern days, helps to recover the urban structure from the Feudal Regime. Next, adopt, again, the “Surveying Reference Point” published by the Geospatial Information Authority of Japan, study the historical documents, this research team then is capable of verifying the entire coordinates of mountaintop points from the old town below the castle-crowned mountains.

Secondly, this research team tries to specify the methods by GIS, tackling the relationship between streets, moats and Mountaintop. Thirdly, describe the actual condition of Murakami Castle Town and its urban structure.

Fourthly, the team considers it a mission to verify the “Yama-ate” by inspecting the real historical situation. The particular features of the road to visualize the Yama-ate are collected, made as numerical data; three types of Yama-ate are classified to present the characteristics of each Yama-ate. About the Object Mountain, the culture-historical literature since the middle age are reviewed and researched.

In the light of the above action, the urban structure and Yama-ate of Murakami city may become manifest.

Previous researches

Besides the documents 1) and 2), 3) mentioned above and the series of group research directed by Agemura and Tsuchida about the castle in Satsuma 4), the research proposed by Takami 5), applying Visual Axis and Vista, as the major design methods, to design modern castle towns. Also, in Kirishiki 6) and 7) the relation between Edo and Mt. Fuji, between Edo and Mt. Tsukuba and between Sunpu and Mt. Fuji was discussed in 8). And further, Yamamoto 9) also discussed the Vista method to frame the castle Turret and the donjon, the castle tower in Sendai, Kumamoto and Hirosaki, including each “Yama-ate.”

All these were done in accordance with field inspection and small scaled maps; a phenomenon, as a piece of verified phenomenon, can be nothing but a reference; the methodology of numerical measurement, investigation on document, reports or historical literature would end up producing another investigation report without precise, edgy and convincing results. Thus so, this paper concerns itself with how to obtain accurate and specific results by means of GIS analysis with documentary investigation in field inspection, and with how to grasp the basic data for the legitimacy or ground to infer the original design intention of the Castle town. Also, Zhao 10) presented the study, using the concept of “landscape corridor,” analyzing the relationship between the castle town and the periphery mountain. Higuchi 11) concerned himself with the blocking factors in the horizon, or within the vista of Yama-ate. All these, however, are studies basing on vista methods or documentary literature without the accurate measurement as the legitimate ground for research. Although Takamori’s researches, 12), by computing the topographical data and information collected from a significant wide region, did work out the “road ratio” of Yama-ate in this region and be approved as significant

level of studies statistically, Takamori's researches were not done by means of specific measurement and mathematic analysis; viz. measuring from the visional point where the viewer stands in the main street, for example, and face the mountain through the visual axis perpendicular to the crowned mountaintop.

Definition of technical usages (Figure 1)

Basing on the usages used in the previous researches, their definition are given below:

1. Object Road: The Road, Moat or River verified in the Vista of Yama-ate and Turret.
2. Object Mountain: the Mountain that faces the Object Road.
3. Field of Vision (point a): the starting point in the center line of main road that faces the Mountaintop.
4. Center Point (point b): the Vanishing point in the center line of main road that faces the Mountaintop.
5. Mountain Top (point P): the top of triangulation point is the Mountaintop, or the coordinates of Mountaintop.
6. The Center Line of Main Road: The line linking the Field of Vision (point a) and the Center Point (point b) on the ground plan.
7. Mountain Line: The line linking the Field of Vision (point a) and Mountaintop (point P).
8. Internal Angle of Lines: (α) the horizontal angle between The Center Line of Main Road and Mountain Line.

Figure1. Definition of Technical Usages.

About Murakami the Castle Town

Murakami, located on the top north of Niigata prefecture and being adjacent to Yamagata Prefecture, has recently become a contemporary Castle Town with the population of 64,000 (2014).

In the era of Daimyo Honjyo from the mid-sixteenth century till the turn of the seventeenth, the castle was built on the top of Mount Gagyū; consequently several villages got settled in below. The then castle, before Murakami Yorikatsu and his retainers came to occupy it in 1598, was still medieval in style; Murakami started on renovating the castle and his successor carried on to do so. After Hori Naoki entered into a castle in 1618, the Magewa: castle wall design in the time of Murakami Yorikatsu, was expanded, the castle donjon and turret were reconstructed and the moat was rebuilt, fortified to be the sort of (prototype of) Modern Castle Town.

The urban area today has kept expanding around the Murakami subway station of Uetsu line; yet large scaled land division and preparation were not processed except a small portion of streets were expanded in width, the Murakami urban structure remains its shape as a modern Castle Town.

Methods of making the GIS Map Data for analysis

Making the base map

The GIS map-making is processed by ArcGIS for Desktop 10.0 (made by ESRI). The level-2500 scaled Base Map, issued by the Geospatial Information Authority of Japan is selected, and the frame of reference is defined WGS, rectangular plane, eight systems. On 11 March 2011, the super earthquake struck the Northeast of Japan from the Pacific offshore and the earth crust fluctuation, thus, caused the periphery of Murakami city slightly to move off their original longitude and latitude. This map-making is re-corrected and modified in accordance with the official adjustment issued by the Geospatial Information Authority of Japan (land survey report 2011).

Restoration of the urban structure in feudal regime

In order to process the mathematic (numerical) analysis of the urban structure of the Edo period, the urban structure of the Murakami city in the Feudal Regime Era was restored in level-2500 scaled Base Map. Three grand restoration projects include the following: i) to specify the location of the historical roads before their expansion and ii) to work out the disposition of castle moat, fort and castle gate and prepare the division of land use.

The specific plans to restore these projects are the following: i) reading the inspection drawings plans inscribed in the 56th year of Showa era (1981) about the width of road expansion, this research subdivides these plans – from the dawn of Meiji Era (1868) till 1981 – and then compares these 1981 plans with the expansion width in the inspection drawings plans collected in the modern Maps of Land Registry issued by the Legal Affairs Bureau. Through such comparison, the original locations of the roads before expansion may be restored and inscribed on the Base Map; ii) using the GIS tracing function, the two-layer map – piling the early Meiji Era castle town map onto the map today² may be more accurately represented.

Specify the mountain top coordinates

Basing on the “surveying point of reference” issued by the Geospatial Information Authority of Japan, the data of mountaintop coordinates can specify the entire Mountaintops (point P) and let all the Mountaintops (point P) be visible from the entire area surrounding the castle on the mountain. Yet, since the Mountaintops with the same coordinates stand among different

locations, this research also checks the mountain coordinates – the Sea Level Heights of Major Mountains in Japan (recorded by the Geospatial Information Authority), adjusts the errors and specifies the Mountaintop coordinates.

Yama-ate and its analytic methods by GIS

Visual field inspection

On September 2013, this research group did a field inspection about the roads found in the Murakami drawings completed in the Early Meiji Era, seeking verify if these “object roads” may provide Yama-ate mountain views. Meanwhile, to grasp the “starting point” and the “vanishing point,” where the mountain view appears from the road or disappear owing to the bending or curving mountain shapes.

Specify the Yama-ate by GIS (Figure 2)

The city road structure of Murakami town remains, basically, as it was in the time of Feudal Regime, except that the waterways connecting the castle moat were already buried. Also, several high-rise buildings do stand along the road, hindering the Mountain View from the road. With regard to this, the mountaintop (point P) is written down in the postscripts of Base Map and connected with the center point of main road – the point of Field of Vision (point a) – of the street blocks and moat embankment. This connected line between “point a” and “point P” is written as Mountain Line in the Base Map, and in the places where the street crossings or junctions are absorbed by the width of road expansion, this road regarded as Yama-ate. The adjacent city blocks and moats that match this condition, the line was regarded as one sequential Object Road face the Mountaintop (point P).

Figure2. Specify the Yama-ate by GIS.

Computation of Interval Angle (α) and Elevation Angle (β)

The center point of Moat, the starting point and vanishing point of the Object Road are various center points (point b) in the field of vision (point a), and these points are linked up to be the Center Line of Main Road. And, as for the Roads that were expanded in width, the center line of the road before width expansion must be put in the Base Map. Then, make the Mountain Line by connecting the Mountaintop (point P) and the Field of Vision (point a). Compare both Center Line of Main Road and Mountain Line, calculate the tolerable errors of horizontal angle of both Lines and yield the Internal Angle (α) of Lines. That is, if (α) is smaller, the castle-crowned mountaintop can thus be visible from nearer place of the center line of Road and Moat.

Still, from reading the 5-meter mesh information closest to the Field of Vision (point a), the sea level heights can be made, and the numerical difference of sea level heights between point (a) and (P) can be calculated. This numerical value, together with the horizontal distance

between (point a) and (point P), the elevation angle (β) from the Field of Vision (point a) up to Mountaintop (point p) can be calculated.

Actual Condition of the Yama-ate viewed from the Object Road (Table 1)

From the results of the Yama-ate analyses via the analyses methods above, 24 cases of Yama-ate may be verified from seven Object Mountains: Mt.Wahsigasu, Mt.Nakadake, Mt.Takatori, Mt.Kokuzo, Mt.Sankyo, Mt.Geto and the Mountain without Name. And, the internal angle ranges from $0.028^{\circ} \sim 4.774^{\circ}$ with an average of 1.09° , the elevation angle from $3.014^{\circ} \sim 9.501^{\circ}$ and average of 5.41° . The details follow.

Table1. Numerical Analysis Yama-ate, and classification of Object Road

Pattern of Object Road	Name of Object Road	Object Road			Object Mountain Top		Object Road – Object Mountain Top				
		a-b Distance	Angle of the Center Line of Main Road	Elevation	Name	Elevation	Angle of Mountain Line	Internal Angle of Lines	a-P Distance	a-P Difference of Elevation	Angle of Elevation From point a
		m	(a→b) Degree(°)	(point a) m		(point P) m	(a→P) Degree(°)	< α > Degree(°)	<X> m	<Z> m	< β > Degree(°)
1.The Main Town Roads built in Straight Line	a.The Koshindo Line	261.4	13.5	8.8	Mt.Kokuzo	463.0	13.7	-0.175	8,585.6	454.2	3.029

	b.Kawauchi Shrine Line				Mt.Geto	237.8					
	c.Kannonji Temple Line				Mt.Geto	237.8					

Classification of Object Roads

There are six types below, from classifying the special features and forms of Object Roads.

1. The Main Town Roads built in Straight Line

It refers to the Road built along the front side of the street building for more than 200 meters. There are eight cases of such Straight Line of Main Town Road:

1a. The Koshindo Line: the Road was built facing the front façade of Koshindo Hall, which was built at the Gate of Katamachi Gate as the Defense against Evil Spirit; both Mt.Koshindo and Donjon are visible from the Koshindo line.

1b. The Akiba Gate – Korinji Gate Line: the line was built in the Samurai Residence, linking the Gate of Akiba and Korinji; it faces the Mountain Without Name.

1c. The Fukuro Gate Line: the Road was built by extending the Fukuro Gate and parallel with the 1b line by a slight tolerance of 0.20° . The internal angle of Fukuro Gate Line is smaller than 0.33° . The Mountain without Name is visible as well.

1d. Koishigaki Gate – Nakano Gate Line: the road was built in a Samurai Residence, connecting Koishigaki Gate and Nakano Gate; Mt. Sankyo is visible from the South.

1e. Nagaimachi – Komachi Line: built on the Hokkoku Highway, it is the longest line, 754.7 meter, of the south-north bound; Mt. Geto in the North and Mt. Sankyo in the South are visible. Both ends of the line are bent into Key shape, respectively connecting the South Outer Moat Gate Line(4e) and North Outer Moat Gate Line(4f).

2. The Waterway built in Straight Line

These man-made Waterways, or Moats, were built with embankment for castle protection and river improvement, extending in straight line for more than 200 meters. There are four cases as:

2a. Koishigaki Gate – Nakano Gate Moat Line: the Moat connecting Koishigaki Gate and Nakano Gate faces Mt. Sankyo in the South. It is adjacent to, but not parallel with, 1d Line by an error of 4.57° .

2b. Fukuro Gate – Akiba Gate Moat Line: It connects Fukuro Gate and Akiba Gate, about 91.1° perpendicular to Mt. Wahsigasu in the true East.

2c. Main Gate – Inno Gate Moat Line: It connects Main Gate and Inno Gate, facing Mt. Sankyo in the South. It is parallel with the 1e Line by a small error of 0.78° .

2d. Main Gate Moat Line: It was built north to Main Gate, facing Mt. Takatori in the North, being adjacent to 1e Line but sliding away by 2.71° . Also, the 2c Line, sliding away by 3.49° , is connected within the territory of Main Gate, and the Moat at the Main Gate is hugely bended.

3. The Town Roads build as Side Street in Straight Line

It refers to the town road built along the side façade of town buildings; the center line of such type of Side Street intersects the Straight Town Road along the front façade. There are three cases of such Side Street.

3a. Akiba Gate Side Street Line runs from Akiba Gate toward Mt. Sankyo in the South. It interests the 1b Line by 94.1° and the 1c Line by 85.7° , sliding away from the 90° angle by more than 4° .

3b. Geto Gate Side Street Line starts from Geto Gate and runs towards Mt. Sankyo in the South; it interests the 1c Line by 93.4° instead of 90° angle.

3c. Samurai District Side Street Line was built in the Samurai Residence outside of bailey and runs towards Mt. Sankyo. It interests the main town road by 88.2° .

4. Key-typed Road

It refers to the short span Town Roads shorter than 100 meters, featured with its bent form in key shape at the end of road, and there are eight cases of such types of Road Line.

4a. De-yagura Turret Line: the line was built on a historical Highway; Mt. Takatori in the North and the De-yagura Turret of Mt. Gagyū in the south may be seen without hindrance.

4b. Yuki-yagura Turret Line: the line was also built on a historical Highway; Mt. Takatori and the Yuki-yagura Turret may be fully seen.

4c. Highway Line: the line was East to 4b Line, bending toward the East and facing Mt. Nakadake.

4d. Wahsigasu-key-typed Line: unlike other lines which are bending almost in right angle, this line changes direction only with the town street.

4e. South Outer Moat Gate Line: it connects 1e Line south, facing Mt. Sankyo

4f. North Outer Moat Gate Line: it connects 1e Line north, facing Mt. Geto.

4g. Temple District Line: the line connects Temple district and the territory/border of merchant district, facing Mt. Geto.

gh. Gate Line: it links 4d Line and bends itself with the Highway in the north, Mt. Takatori is fully visible over the gate.

5. The Key-shaped Waterways

It refers to the short-spanned Waterways or Moats under 100 meters typically built with bended form at either ends of the water.

5a. Moat Gate Line is the only example, it gets bended in the form of Gate and flows toward the direction facing Mt.Washigasu.

6. The Sando in Shrine as Worshipping Path

The Sando in Shrine is the road built on the Axis that connects the Torii as its entrance and the Main Hall. There are three cases:

6a. Fujimoto Shrine Line: from the Sando, Mt.Geto is visible in the North.

6b. Kawauchi Shrine Line: from the axis that links Torii and Main Hall, Mt. Geto is visible.

6c. Kannonji Temple Line: the axis of Kannonji Temple runs towards Mt.Geto.

Three major types of Yama-ate (Figure 3)

Basing upon the differentiations of the six kinds of Object Roads discussed above, three kinds of Yama-ate may be classified from analyzing the relation between the shape of each Object Mountain and the Roads in the periphery.

a) The Yama-ate facing the Mountaintop with precise, straight Axis

Following the patterns of Straight Town Roads and Straight Waterway built, each Object Road that made the major framework of Castle Town is in long span and independent from other Object Roads; e.g., axis for defense against evil spirit (Ghost Gate) and axis links the Castle gate, the Southeast Axis of Highway. Disregarding the 1e Line, the axis of the Object Road in the Vista towards Yama-ate has very small angles – from 0.035° to 0.716° ; on the one hand, the average internal angles of these three Mountain Lines facing the cone-shaped, visibly easy Mt.Kokuzo, Mt.Washigasu, Mt.Takatori is 0.25° , which is accurate. On the other hand, the average internal angle of those five visibly uneasy Mt.Sankyo, Mt.Geto, Mt.No-name is 0.50° , which is a big deviation. Also, the internal angle of the 1a Line, from Donjon to the Ghost Gate (of Northeast orientation) is -0.175° , a straight mountain line toward Yama-ate.

b) The Yama-ate facing the Mountaintop with adjusted Axis

The Axis of the Key-typed Road and the Key-shaped Waterways are twisted owing to the bended part at the end of the line, and from the end of either road or waterway the mountaintop and castle turret are visible. Also, the Straight Side Street that intersects the Straight Town Roads fails the 90° right angle by the errors of $1.8^\circ \sim 4.1^\circ$ and let the Mountaintops be visible. And also, the Sando built on the Axis connecting Torii and the Shrine's Main hall was adjusted to let the Mountaintops be visible.

c) The Yama-ate facing the Mountaintop with sliding Axis

Although both Mt.Sankyo and Mt.Geto are visible from the 1e Line, the mountain lines have the internal angles of 3.093° , 4.774° – the only Town Roads built in Straight Line that slides from its Axis gravely. And yet although each Mountaintop is vanished from either ends of the 1e Line, from both 4f Line and 4e Line that link the 1e Line, these Mountaintops of Mt.Sankyo and Mt.Geto are visible.

Closing comment

Basing upon above, the specific features and characters of each Yama-ate in Murakami may be concluded as the following three points:

First, each of the Object Roads that made the major framework of Castle Town are not parallax to each other, and thus from each Vision Axis the Yama-ate can be recognizable and, furthermore, since the Vision Axis is accurate, the mountain scenery is easily visible.

Second, the Straight Side Streets and the Key-shaped Roads intersect the Main Town Roads fails the 90° right angle, for the Vision Axis has to be adjusted in order to face the Mountaintop. And, the Sando starting from the Torii and lining to the Main Hall must also be adjusted to face the Mountaintop.

And third, the Visual Axis that is gravely slid from the Mountain Line, its Yama-ate offers appearing and disappearing mountain views.

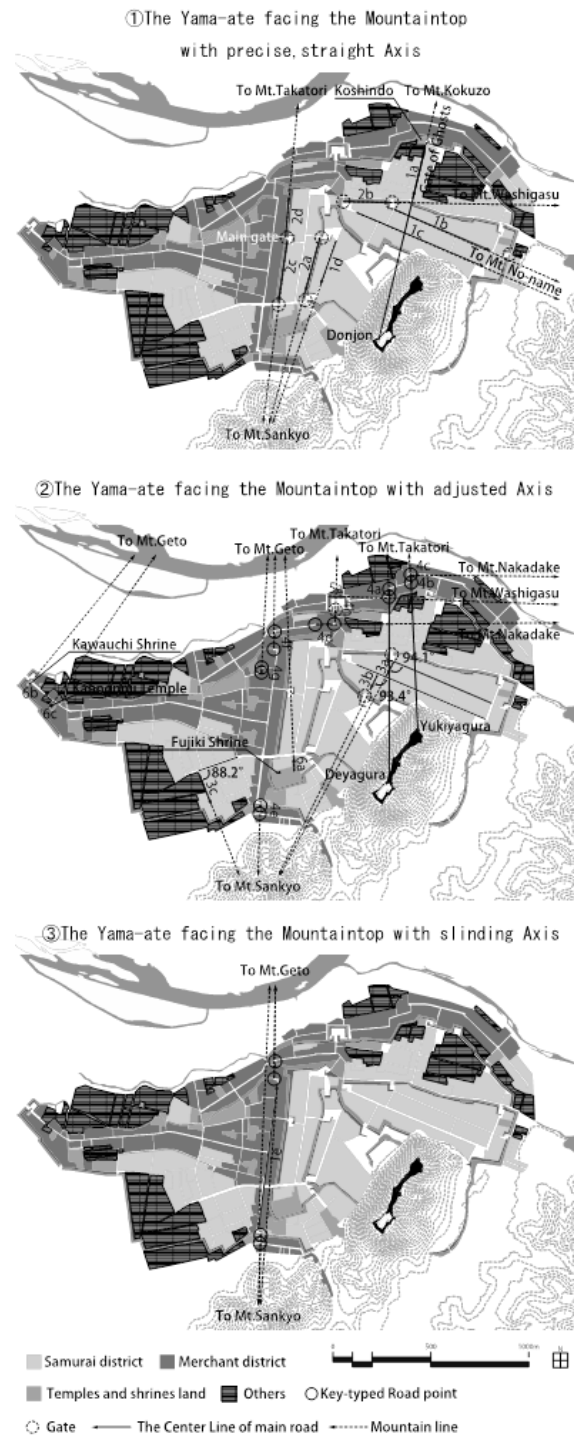

Figure3. Three major types of Yama-ate.

Between the Object Mountains and Murakami – culture aspects on Documentary Literature

Although there are seven Object Mountains appearing in the respective Yama-ate, in this section this research wishes to make manifest the significance that how the Object Mountain has any relation with the local culture.

The Belief in Animism, Water God, Goblin or Water Sprite in Miomote-River Basin

Mt.Washigasu has been enshrined by *Washinosu Gongen* – literally the Gongen in the Eagle's Nest (and Gongen refers to the Buddha that appears as *Kami*, the Japanese deity in Shinto) – deified in Mountain cave some 1093 meter above sea level in the Satomiya Shrine that was joined by Kawauchi Shrine in Nunobe, in which the *Daimyōjin Kami* is deified. The Kawauchi Shrine has two divisional shrines: the Ichinomiya Shrine Miyanoshita and Ninomiya Shrine Nunobe.³ The Nyorai Buddha of Medicine used to be deified in Ichinomiya Shrine, is now deified in Mt.Takatori. The Nyorai Buddha of Medicine is also deified in the Nakadake Height of Mt.Washigasu.⁴ Since the middle age, the belief in Animism has deeply rooted and thus, Kawauchi Shrine has been strongly associated with Water Deity, Goblin or Water Sprite in local belief. And also, since the old days, “the people living in the basin of Miomote-River and its tributary had very unusual relation with rivers and salmons,”⁵ it was believed to be their “Salmon Culture.” According to the history of Ichinomiya Shrine, worshipping the Water God – Ishigami – whilst sailing along the rivers has been their tradition.”⁶ From these cultural aspects, the belief of Water Deities in Kawauchi Shrine, the Shinto ceremony in Miomote River and the festivals inherited from the “Salmon Culture” become the culture heritage today.

Relation with Compass Direction of belief

The Mt.Kokuzo is located in Sarusawa of Murakami City, marked with its 463.0 meter above sea level; the Bodhisattva of Kokuzo has been deified in the Mountaintop. The annual ceremony, as written in the city history, section 3, of Murakami, has been carried out by every village, “paying respect to Bodhisattva of Kokuzo, give a wish in the Spring and pray in the Autumn with one-syo (1.5 kilogram) unhulled rice one village.”⁷ The significance of Bodhisattva of Kokuzo, as rooted in the Murakami region since the old days, is profound and beautiful. Ox and Tiger, the second and the third in the twelve horary signs, respect Bodhisattva of Kokuzo as the protector of the people born in the year of Ox and Tiger, yet the direction where Kokuzo Bodhisattva exists is Northeast, and it is commonly believed that the Northeast direction on compass is the Gate of Evil Ghosts. Therefore, the Katamati Gate that faces the Northeast has built Koshindo to pray for protection from Bodhisattva of Kokuzo to guard the people in the Murakami Castle Town.⁸ It is clear that the Koshindo Line was designed with strong Buddhist consciousness to face Mt.Kokuzo, when the Castle town was planning.

In the painting “*Senami Gun Ezu*”⁹, 2nd year of Keicho (1597), it showed that Mt.Washigasu was noted as True East from Murakami. It is clear that the sense of sunrise direction is strong.

Land Boundary Orientation seen from the Sea

“The fishery spots of Miomote-River and Senami are ‘where Mt.Washigasu seems to be visible.’”¹⁰

Also, the methods to use Yama-tate (not Yama-ate), Mountain as location reference to verify the reefs and half-sunken rocks, the mountain saddle of Mt.Nakadake has been used for references for sailing direction.¹¹

The Location Relation between Castle and Tomb

As noted in *Ethnical History of Murakami Region, II*, “Mt.Sankyo may be the places for public tombs” In fact, the place that was used as burying ground was called “Sanmai”¹²(a word in Zen, synonymous with Nehan: Nirvana, or Gedatsu: emancipation) in the history of Murakami, and the fact that temple and communities were formed around the foothill of Mt. Sankyo, and the story that Naito Nobuteru, the feudal Lord, was cremated in Ushizawa, the east point of Mt. Sankyo, were all written in the history of Murakami and became clear in this research.¹³

Also, the Getogashima Castle, the sister castle of Murakami Castle in Mt.Geto, was built in the middle age; it was written in the painting “*Senami Gun Ezu*” and became clear.¹⁴

Conclusion

This research concerns itself with the actual conditions of Yama-ate – and with the interrelation between these issues and the issues of Road and Moat; this research, employing the mathematical analyses of GIS in field inspection for unbiased, objective results, tries to make the actual conditions of these issues become manifest.

In doing so, this research pinpoints Yama-ate as the major theme and tries to classify different Object Roads into six categories from their differences in feature and shape, bringing up 1) the Main Town Roads built in Straight Line, 2) the Waterways built in Straight Line, 3) the Town Roads build as Side Street in Straight Line, 4) the Key-typed Road, 5) the Key-shaped Waterways, 6) the Sando in Shrine as Worshipping Path.

Yet, basing on the results obtained from analyzing the numerical data and the types of Object Roads, the Yama-ate of Murakami has three characters: 1) as the major framework of Object Road, it holds a specific Visual Axis, 2) as the right-angle intersection of the periphery roads get twisted, the Vision Axis is adjusted to face the Mountaintop, and 3) as the Vision Axis slides sharply, the appearance of Mountaintop become vague and unpredictable.

Lastly, this research, concerning the Object Mountains verified by Yama-ate, believe in, also, the necessity to make these Object Mountains manifest by searching their historical literature, poetically. Thus, there are four points worth of our attention: 1) the belief of Water God in terms of Animism in Miomote River, 2) Compass Direction of belief: the design motivation of the Yama-ate that faces Mt. Kokuzo, in particular, is of Buddhist consciousness – defending against the evil spirits coming from the Ghost Gate in the Northeast compass direction. 3) The location and boundary as seen from the sea, and 4) the distribution of ancient tombs and castle.

These four points are culturally relevant to Mountains and Murakami as a whole; and the historical, cultural and religious aspects of their environments are inseparable from their life on a day-to-day base.

Measuring Urban Canyons with real-time light based Sky View Factor Modelling

Marcus White, Nano Langenheim

Faculty of Architecture, Building and Planning, The University of Melbourne,
VIC3010, Australia. E-mail: mrwhite@unimelb.edu.au, n.langenheim@unimelb.edu.au

Abstract. *Many Australian cities are currently experiencing rapid urbanisation and densification with the unintended consequence of creating dense city fabric with deep urban canyons. Dense urban areas have a profound impact on the local atmospheric conditions in particular, the urban heat island (UHI) which can increase temperatures within urban centres considerably when compared to surrounding rural areas. As Australian cities are presently experience record heat waves with temperatures in excess of 40 degrees Celsius for five consecutive days, there is a critical need to better understand urban form and heat retention in city centres – urban heat island effect (UHI) and the associated heat related morbidity. This paper describes the development of a new three-dimensional analysis approach based on a modified daylight modelling system to improve an established method of UHI prediction – sky view factor (SVF). A rapid SVF is calculated in a digital modelling and visualisation environment allowing iterative design decision making informed by UHI and SVF impacts on an urban design scale. The new technique provides ‘real-time’ SVF feedback for of complex three-dimensional urban scenarios enabling city designers to have a greater understanding of existing and proposed urban forms and identifying potential UHI problem areas; improve decision making, community engagement and design advocacy; potentially have an impact on city’s temperature – reducing cooling energy load costs; and more importantly, potentially reduce heat related mortality.*

Key Words: Sky view factor, urban heat island, urban canyon, urban modelling, liveability.

Introduction

Densification / urbanisation

Many Australian cities are experiencing rapid urbanisation densification (DOI 2012). Though there is a greater understanding of the relationship between densification, transport, and sustainability (Beatley et al. 2009; Newman & Kenworthy 1999), there is also great pressure to accommodate higher population densities in established, well serviced, inner urban areas (Dodson & Sipe 2008) often in the form of high-rise developments. These forms of development may be more sustainable environmentally (Newman 2006) and financially (O’Hara 1997) but may also have the unintended consequence of creating a denser urban fabric with deep, heat retaining urban canyons.

Heat waves and heat related mortality

Dense urban areas have a profound impact on the local atmospheric conditions in particular, the urban heat island (UHI) which can increase temperatures within urban centres considerably when compared to surrounding rural areas (Basara et al. 2010; Mills 2004; Oke 1988; Oke 1981). This heat retention in urban centres has been understood and documented since the late 1960s (Bornstein 1968).

Heatwaves are among the deadliest of natural disaster types (Li & Bou-Zeid 2013). The 2003 death toll in the European heat wave of summer 2003, probably the hottest in Europe since AD 1500, resulted in around 70,000 heat related mortalities (Lass et al. 2013).

Australian cities are particularly susceptible to impacts of climate change with increasing extreme weather events such as heat waves (Patz et al. 2005). Heat waves are likely to increase in frequency, intensity and duration as a consequence of climate change (Akompab et al. 2013). According to Victoria's Chief Health Officer Dr John Carnie, the 2009 January heatwave resulted in around double the number of fatalities than attributed to the tragic Black Saturday bushfires (Victoria 2010).

As Australian cities are presently experiencing record heat waves with temperatures in excess of 40 degrees Celsius for five consecutive days this year; last year being the hottest on record (BOM 2013), there is a critical need to better understand urban form and heat retention in city centres – urban heat island effect (UHI) and the associated heat related morbidity. The level of seriousness with which this issue is now taken is evidenced by the City of Melbourne's Urban Forestry Strategy document (Melbourne 2012).

The urban heat island (UHI)

Urban and suburban areas experience elevated temperatures compared to their outlying rural surroundings; this difference in temperature is what constitutes an UHI (Wong & Hogen 2011). Temperature differences between central urban areas and nearby rural areas can range from 2°C to as much as 12°C on a clear and calm night (Wong & Hogen 2011).

The UHI effect can intensify extreme climatic events (Patz et al. 2005) and has been found to be a major contributing factor to heat-related mortality in urban regions, acting to worsen the adverse health effects from exposure to extreme thermal conditions (Luber & McGeehin 2008; Tan et al. 2010). For this reason, along expected extreme weather conditions of climate change, UHI is a key consideration in the design for the growth of cities in the future.

The UHI and urban canyon modelling using sky view factor (SVF)

The modelling of UHI is extremely complex (Shao et al. 2011) with a great number of variables such as wind, material colour, street orientation, tree coverage, permeability of ground surfaces and building heights in relation to street width or "urban canyon" (Oke 1988).

The urban canyon, considered by some to be the most important contributing factor (Ibrahim et al. 2011) to the UHI effect, is the focus of this paper. The urban canyon is where, in dense urban environments, buildings on each side of a street enclose a space obscuring the sky and therefore restricting the amount of long-wave radiation that can escape, a phenomenon particularly acute at night (Wong & Hogen 2011). The measure of the degree to which the sky is obscured at a given point is commonly calculated as either Height to Width ratio (H/W) or as Sky View Factor (SVF) (Watson and Johnson, 1987). SVF has been found to be a more effective measure as it can take into account the complexity of real streets in which buildings are irregularly aligned and which vary in height and length (Johnson & Watson 1984).

SVF is a dimensionless measurement of openness between 0 and 1, representing totally obscured $\Psi_{\text{sky}}=0$ and totally open spaces $\Psi_{\text{sky}}=1$ where the sky is completely unobstructed by obstacles allowing all outgoing radiation to radiate freely to the sky (Figure) (Brown et al. 2001).

SVF as a method for modelling has been shown to have a strong correlation with UHI (Brandsma & Wolters 2012; Ewenz et al. n.d.; Kakon & Nobuo 2009; Unger 2009) and is critical to understanding the impact of densification and urban form.

Figure 1. “Urban canyon” or sky view factor calculated for a single point using projected rays through the single point and surrounding building form, intersecting with a hemisphere to assess level of ‘openness to the sky’.

Modelling SVF

SVF has traditionally been very difficult to measure (Grimmond et al. 2001). There are however several methods for modelling and assessing SVF. Unger (2009) lists five common modelling methods as:

1. scale model (Oke 1981);
2. analytical method (angle measurements, H/W),(Bottyan & Unger 2003; Johnson 1985; Johnson & Watson 1984);
3. manual and computer evaluation of fisheye photos (Blankenstein & Kuttler 2004; Bradley et al. 2001; Holmer et al. 2001);
4. evaluation using GPS signals (Chapman & Thornes 2004);
5. and computationally evaluation using digital elevation database describing surface geometric elements (Brown et al. 2001; Lindberg 2005; Souza et al. 2003). There are also developments on this method of generating SVF with the use of Lidar aerial mapping with raster based three-dimensionalisation of two-dimensional data using Digital Elevation Models in GIS (Kokalj et al. 2011).

In addition to these methods, tools used in forestry to measure leaf area index such as the *LAI 2000* have been suggested (Grimmond et al. 2001). There are also relatively recent microclimatic modellers such as SOLWEIG and Envi-Met which can be used to analyse a low detail street canyon to a resolution of 0.5 m (Levermore & Cheung 2012).

Each of these methods has been shown to have a reasonable level of accuracy, but vary greatly in speed of application and ability to test and assess complex three dimensional ‘what if’ scenarios.

Scale models involve a lot of manual labour in assembly and fish-eye photography, though very accurate, are extremely time consuming to acquire and process even with greatly improved software (Brown et al. 2001) and is limited to assessing specific points of interest in an existing urban context.

The “analytical measurement” angle measurement or “height/width” method of assessment is problematic as described above, as it is a purely two dimensional sectional method, not taking into account the complexities of a real street where a section may change dramatically along its length.

Other digital modelling methods such as those described by Brown, Grimmond and Ratti (2001) can be applied and computed more rapidly to a resolution of a 2x2 metre grid, though restricted to using Digital Elevation Models which are essentially two dimensional with a height attribute (2.5D), meaning that they cannot assess more complex three dimensional urban forms such as where a street has weather protecting canopies at lower levels or has elements of buildings that may cantilever or protrude from a building at an upper level.

Where fully three dimensional GIS models have been assessed using hundreds of rays projected from a series of points (Chen et al. 2012; Kastendeuch 2013; Kidd & Chapman 2012) it has been computationally intensive – requiring powerful hardware taking up to 10 hours to assess a precinct (Gal et al. 2009; Unger 2009).

Aim

The aim of this investigation is to develop and test a new three-dimensional analysis approach for SVF that provides rapid visual and numeric feedback in a 3D modelling and visualisation environment. The method is required to allow iterative urban design decision making informed by UHI and SVF impacts on an urban design scale.

Method

The method we have used to develop and test this rapid three-dimensional SVF analysis technique involved four parts. Firstly we ‘hacked’ common animation and visualisation software’s daylight modelling system to create a ‘sky dome light’; secondly we reconfigured a 3D software based lux level light meter grid so that the maximum light level value was equal to 1 and the minimum value equal to 0 to match the SVF metric; thirdly we verified the readings of the SVF modelling against a simple mesh area mathematical based model; and finally, we tested the tool’s applicability at a large urban scale – applying the tool to the Melbourne central activity district using relatively low-end computer hardware.

Results

‘Hacked’ photometric daylight system modelling - sky-dome light

Instead of starting with the point of interest and projecting rays outwards to intersect with surrounding geometry and then a hemisphere beyond (Unger 2009), the logic was reversed – rays start on the surface of a hemisphere and are projected inward to the point of interest. To achieve this model, we use a hemispherical light source – a “sky-dome” or “Skylight Illumination” which projects and traces photons (light) from the globe towards the point of interest. Where no obstacles are present (eg. in a desert), 100% of light of the sky-dome illuminates the point of interest – the equivalent of $\Psi_{sky}=0$. Where photons are blocked by obstacles (buildings), shadowing occurs and SVF is reduced to <1 . This process was done using the render engine within common modelling, animation and visualisation software (in this case we used Mental Ray render engine within Autodesk 3dsMax™) which is able to trace millions of photons (Grosch 2005), a process normally used to produce photo-realistic rendering of digital 3D objects and scenes.

To achieve the sky-dome as light source to model SVF, we reconfigured the standard photometric daylight modelling system. The standard day lighting system would normally consist of a direct light source from the sun, global illumination from the sky (intensity derived from weather data) and indirect/ambient light bounced from other objects in the scene. Our method modified the settings to set the intensity of the sun to zero (no direct light from the sun as though the sun was turned off), set an artificial uniform low intensity light from the sky (dome), and set the number of bounces of photons possible to zero (light is not reflected by any object within the scene). With this ‘hacked’ sun system setup, surface areas of the model that received full global illumination (full 180deg of light from the hemisphere) appeared white ($\Psi_{sky}=1$) when rendered. Where the surface is in shadow it appeared as a shade of grey depending on the amount of shadowing of the sky-light by other objects or black where it receives no light ($\Psi_{sky}=0$) when rendered.

Figure 2. LHS diagram showing common method for calculating SVF using rays from a central point. RHS diagram showing reversal of logic, rays starting at surface of dome projecting inwards towards central point.

Figure 3. Sequence of test screen grabs of four boxes (buildings) with height parameter changed – the higher the boxes, the darker the shadowing and lower the SVF level.

‘Real time feedback’ with interactive geometry

This method of testing SVF has had rapid results using the built in Mental Ray™ render engine. SVF for complex urban scenes including buildings, streets, street furniture, canopies etc. were rendered in as little as a few seconds depending on the size and complexity of the geometry. Relatively recent improvements in quality of viewport previews of materials, lighting and shadows within the view ports with the Nitrous™ viewport drivers (Murdock 2012) meant that this SVF modelling method was able to be employed in the modelling environment with real-time visual feedback (or close to real time depending on the quality of computer’s graphics card). Viewport display modes could also be configured in such a way as to display a model’s SVF ‘shadows’ as a kind of ‘heat map’ meaning that as an urban modelling parameter such as height limit is changed in the model, the impact can be instantly assessed visually.

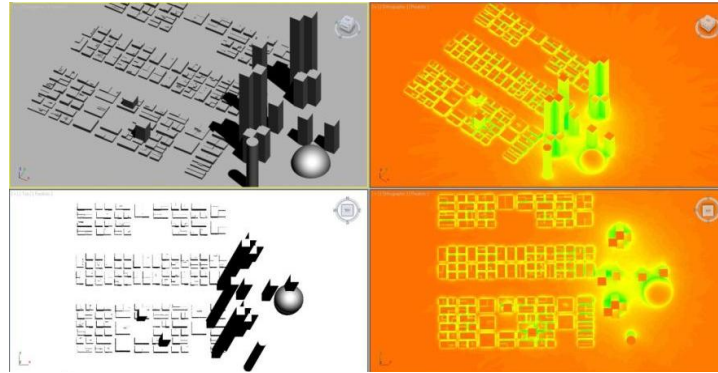

Figure 4. Test screen grab 1 showing an indicative area of tower development with adjacent low level urban form with levels of SVF on the RHS. Note: tops of buildings and open areas are red/orange (high SVF) and areas between towers are green (low SVF).

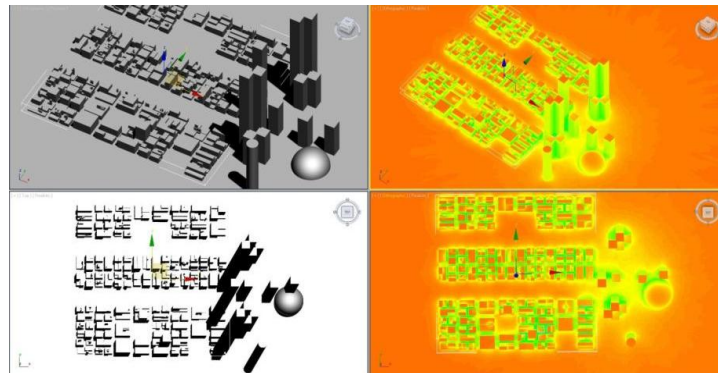

Figure 5. Test screen grab 2 showing an indicative area of tower development with adjacent medium level urban form with levels of SVF on the RHS. Note: slight increase in areas of green (low SVF).

Figure 6. Test screen grab 3 showing an indicative area of tower development with adjacent high level urban form with levels of SVF on the RHS. Note: High coverage of green colour equating to very low levels of SVF.

Lux metre reconfigured so maximum = 1, minimum = 0

In addition to on screen visual feedback and being able to render to a high resolution raster image file (.jpg, .tif, .tga etc.), we also set up the model to use an adapted light meter grid utilising the program's advanced light meter calculation system (Reinhart & Breton 2009). The

Verification using mesh dome % test

To verify the accuracy of the sky view factor metres (reconfigured lux meters), we modelled a series of large mesh domes, each with a 300m radius. Each of these domes was then altered to remove portions of the polygon mesh to a known area percentage – beginning with 50% (Figur). We activated the SVF meter and the resulting SVF readings were each within ± 0.01 of the expected 0.50Ψ reading (0.51, 0.50 and 0.51 shown in Figur).

We performed the final test with a more complex 3D mesh with a simulated skyline to either retain or remove the dome's polygons. The area of the full dome was measured and compared with the modified skyline dome area. The area comparison showed that 34% of the polygons of the mesh dome retained, thus that the SVF meter should result in a $SVF=0.66\Psi$. In this case the reading was within ± 0.03 . This was seen as an acceptable range of error for urban scaled modelling and though a higher degree of accuracy would be possible by increasing the number of photons or the quality of the rendering by increasing the density of light photons, we believed this was not worth the potential sacrifice in speed of feedback.

Figure 10. 3D mesh dome with 50% of the polygon mesh removed. Each of these domes should block 50% of the sky and thus result in a $SVF=0.5\Psi$. The SVF reading for these three tests were within ± 0.01 .

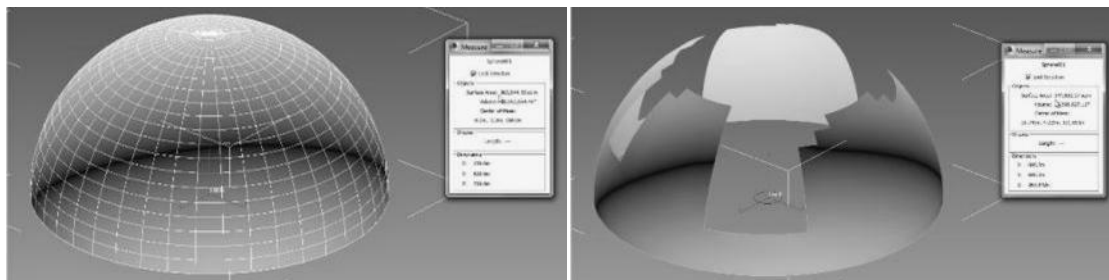

Figure 11. LHS showing full dome with surface area calculation. RHS shows simulated skyline with area measured for comparison to full dome, then compared with SVF meter (in the central point of the dome) resulting in a reading within ± 0.03 .

Validation – testing on Melbourne central activity district

To test the applicability of the tool at a large scale, we conducted a quick test using a 3D model of Melbourne's central activity district. The 3D model was a mix of modelling done in Trimble's Sketchup™ Autodesk's AutoCAD™ and 3DS Max™. The application of the tool was relatively straight forward requiring the different components of the central activity district 3D model to be imported/merged into the preconfigured SVF scene. We then activated the SVF viewport and within 15 seconds a comparative SVF was visible.

The resulting viewport display gave a clear indication of the levels of SVF in different areas of the city at street level with areas that experience low levels of SVF displayed. The other aspect that was interesting is the 3D aerial view the model not only showed what the SVF was at ground level, but also gave an indication of the SVF for sides of buildings indicating where walls were visually shadowed by other tall buildings. This means that areas of building façade could also be assessed for SVF.

The analysis shown in Figure 12 and Figure 13 was performed on a relatively low-end, two year old HP Pavilion dv6-6138TX laptop with a 2 GHz Intel Core i7-2630QM processor, 8 GB Ram and an ATI Radeon HD 6770M (2 GB GDDR5) graphics card. We then tested the same model on a 2013 model Metabox (Clevo) laptop with an Intel Haswell 4 i7-4940MX 3.10GHz 32GB 1600MHZ DDR3 Memory NVIDIA GeForce Go GTX 880M 8GB (higher performance graphics card and more ram) which resulted in instantaneous visual feedback – essentially 'real-time' as changes in the geometry were reflected in the SVF display within one or two seconds.

Figure 12. Aerial view of SVF tool applied to 3D mesh model of Melbourne CBD – plan view. Note the areas in green have low levels of SVF.

Figure 13. Plan view of SVF tool applied to 3D mesh model of Melbourne CBD. Note the areas in green have low levels of SVF.

Discussion

Speed and accuracy

The speed of feedback for this method was exceptionally fast. Though the visual feedback was dependent on the quality of the computer's graphics card and ram. A relatively low end laptop could produce visual feedback within a few seconds even for fairly large complex areas of city. The lux meter readings were also calculated in less than 30 seconds. The more powerful hardware yielded even more impressive results.

The level of accuracy was found to be very good when assessing a series of known SVF area of a 'sliced dome' with a maximum error of ± 0.03 . This level of comparison with the Brown et al study mentioned earlier (2001) which, when comparing the digital model to photographic analysis where results were 'very satisfactory, with average values of 0.63 and 0.70 respectively'.

3D Complexity and feedback

The method described has the potential benefits of being truly three-dimensional, allowing SVF analysis of complex urban scenarios allowing urban designers to have a greater understanding of existing city forms and identifying potential UHI problem areas. The method also has the potential of providing almost real-time feedback allowing the SVF analysis to be integrated into a design process as well as have a role in design advocacy used in community engagement. Using this analysis method, urban designers can test the potential impacts of urban additions or subtractions as well as the impact of complex forms of urbanism including cantilevering buildings, stepped building forms, buildings with holes or 'cut outs'.

The rapid SVF feedback also potentially has application beyond UHI modelling. Because of the three dimensional nature of the model – the SVF for building façades can also be assessed. There is potential to investigate the relationship building façade SVF and quality of views from buildings – how much sky can I see from each apartment?

Potential impact

We have shown this research to be potentially useful in Melbourne, Australia, but the method also has great potential for application in many other cities around the world, particular rapidly developing cities in Asia where UHI effect is believed to have an even greater impact on heat wave related mortality rates (Tan et al. 2010).

Conclusion

The new technique provides 'real-time' SVF feedback for of complex three-dimensional urban scenarios enabling city designers to have a greater understanding of existing and proposed urban forms and identifying potential UHI problem areas; improve decision making, community engagement and design advocacy; potentially have an impact on city's temperature – reducing cooling energy load costs; and more importantly, potentially reduce heat related mortality.

An approach on describing the street skyline: a framework for identifying streets spatial significant lines

Hao Yang

School of Architecture and Urban Planning, Nanjing University
Hankou Road 22, Nanjing, Jiangsu, P. R. China, 210093. E-mail: byldhc@126.com

Abstract. *In urban morphology, researchers have developed many methods on describing the characteristics of urban street patterns. However, a simplified representation of urban texture in just two-dimensions, which does not take into account the dimensional property of streets elevation (later referred to as 'metric'), therefore, the topological representation of cities discards precious metric information and is rather limiting. Some researchers have attempted to add the information about the street skyline to study the street configuration. However, when preparing a street skyline for this method, several critical decisions must be made about which street skyline features should be included in the representation and why. Therefore, the present paper draws on postpositivist reasoning to propose a framework for deciding which lines in a street representation are significant for a study and why. The framework contains several levels of representation that are defined and mapped against comparable research agendas. These levels are described and demonstrated using a street skyline from 6 blocks which contains 2 resident blocks, 2 public blocks and 2 mix-use blocks in urban area of Nanjing, China.*

At last, the research chooses the Shape index Compactness Ratio (CR) as the indicator for analysis. The results of the Compactness Ratio (CR) analysis of different representations of the street skyline are used to demonstrate how decisions about significant lines have a direct impact on measures derived from CR analysis. By using different layers to express the spatial significant lines, we can interpret the average and properties of block.

KeyWords: *Street skyline, framework, compactness ratio, segment.*

Introduction

Spatial orientation is a pervasive facet of our everyday life and in spite of over a hundred years of systematic work on space perception researchers could say little about how we knew where in the world we are. (Robert Cohen, 2006)

Since 1960s, researchers have been paying their attention to the feelings and attending to identifying the significant features in streetscape (Kevin Lynch 1960, Jane Jacobs 1961, Arthur and Stamps III 1997, 1999, 2005, Sergio Porta 2005). There have been various methods presented to identify the skyline or the features of streetscape (Jon copper 2003, Michael J. Ostwald 2005, Stephan K. Chalup 2009). However, each of them did not give a reasonable way that the features can be applied to the urban design.

How to apply the study of urban cognition to urban morphology is a critical issue that urban planners and architects both concern about. Most of the urban cognition researchers focus their interest on the sense of space or the significant elements of physical construct. These researches give us some advice that which factor it's delighted or significant to be paying attention to. However, without an indicator indeed which can instruct the urban design actually, although architects have the image of space in their mind while working through drawings but it's difficult to be practice without regard to the indicator.

Different properties of blocks have distinct images in our city which is mechanism by the different demands of form and plane patterns (figure 1), which can be highlighted in the public block and resident block. Indicator is an essential factor of block patterns, and the number of the index has a direct impact on shapes of buildings (figure 2).

Figure 1. (a)Public block (b)Mix used block (c) resident block.

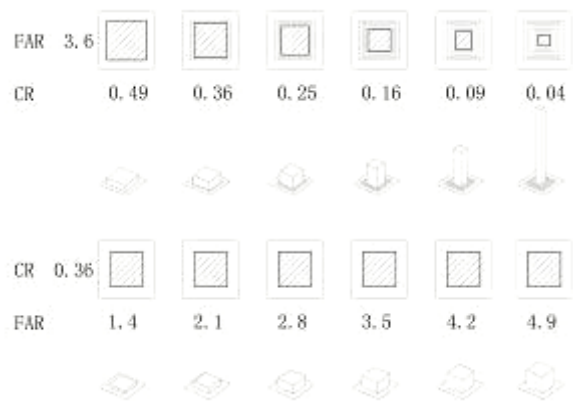

Figure 2. The relationship of the height and Floor Area Ratio and Coverage Ratio.

On the other hand, different views and scale of people analysis the streetscape, different visual features been presented (Ding 2007). At ordinary times, we observe the block by identifying the streetscape which give us deep impression when it looks delighted, when we set our point in urban we may be concern more about the skyline of blocks instead, and we maybe more care about the material and shapes when we live in (figure 3).Even in the same block, the change of the observe position will also bring different visual features.

Figure 3. (a)View from urban; (b) View from street; (c) view when we live in.

Compactness ratio as an indicator

How to define the shape of skyline is very important, some research has calculated the shapes by calculate the fractal dimension (FD) of skyline for quantifying the visual character of the built environment. The version of the box-counting approach that has been used in almost all

architectural and urban analysis is known colloquially by scientists and mathematicians as the “naïve version” (Huang et al, 1994: 339). However, there also have some investigated the question of whether people actually do perceive the fractal properties of fractals or some other properties (AE Stamps, 2002: 6). In actually it has some defect that it cannot identify the shape clustering that means if the shape is very complexity but the fractal dimension (FD) is same to the one is simple (figure 4).

Figure 4. Fractal dimension.

A simple measure of the degree of clustering among sites in a reserve system is the total boundary length of the reserve divided by the area. This is a measure of length per unit area. A more suitable dimensionless measure is the ratio of the boundary length of the reserve system to the circumference of a circle with the same area as the reserve, since a circle is the shape having smallest length for a given area, and is hence the “ideal” boundary length. The formula for this measure is

$$\text{compactness ratio} = \frac{\text{boundary length}}{2\sqrt{\pi \times \text{area}}}.$$

We use this measure of Compactness Ratio to show that the clustering of block skyline, we can define that the higher Compactness Ratio (CR) and the much clustering shape has (figure 5).

Figure 5. (a) circle; (b) rectangle; (c) triangle.

Treatises

A framework

Under the postpositivist paradigm, a legitimate system of inquiry for investigating a research hypothesis must be one for which the key hypothesis can be tested using the data collected for that purpose. Thus, the block buildings features that are represented and measured must be ones which are appropriate to answer the research question. (M.J. Ostwald and J. Vaughan .In order to accommodate this central principle, a framework is proposed where four cumulative levels of representation are defined and mapped against comparable research purposes (Table1) at, for example, a study of the effect of a illegal building on a streetscape is not undertaken by representation the silhouette. Conversely, if the impact of silhouette design such as the turns of wall it will be considered as the properties.

Each of the four levels of representation are described in the following sections and illustrate using variations of an elevation of the same blocks, which are presented alongside the different Compactness ratio measures derived from each. Both silhouette and pattern indicators are used in the analysis, As a silhouette can be considered to provide a measure of the visual complexity

of the blocks as measured from the exterior and the indicator provides a description of the planning as it is inhabited.

Table 1. Levels of representation mapped against research purposes

Level	Representation	Research focus
1	streetscape silhouette	Properties To consider properties and Indicator has the influence on streetscape image
2	interior silhouette	Shape changes To consider the CR changes of silhouette which can distinguish shape changes of interior and External
3	block silhouette	Planning index To consider the relationship of planning Control index and shapes of skyline
4	silhouette overlay	Shapes overlay To consider the background and overlay indifferent blocks the background which enriched our field of visual

Segments

The research choose six typical block (figure 7) which edges is sequential and orthogonal. The properties of block is 2 public use only, 2 mix_used only and two resident use only. For analysis the other properties related there have 2 mix_used blocks appendix in the end. We define the block is the region surrounded by street one is used for pedestrians and automobile .Each of case has been used a few years and located one and the same district. The previous study has confirmed that the coverage of block may have an influence on shape of skyline, so the typical block elected the coverage around 0.4 for analysis which caculated by ArcGis.

Stephan K. Chalup has given the method that simplify the information of streetscape by eliminated the elements of municipal administration(Stephan K. Chalup,2009).The strongest influence on preference, arousal, and pleasure was the degree of silhouette complexity, with higher silhouette complexity associated with higher levels of perceived complexity and preference and higher(Tom Heath,2000).When all three factors were varied simultaneously, the most important factor for visual preference turned out to be the surface complexity. Silhouette complexity was less important, and facade articulation was least important (Arthur E. Stamps III,1999). The findings have direct implications for both practice and research and confirmed that the texture of facade is insignificant in streetscape analysis, and the silhouette is significant for analysis. The results suggest that a very simple physical measurement (percentage of pixels covered by small elements) predicts subjective impressions of architectural detail very well. Other results were that trim was the most influential design component, and texture.(Arthur E. Stamps III,1998) was the least influential design component .We acknowledge that others attributes of buildings such as details at the pedestrian level ,may have greater importance for pedestrians(Arthur E. Stamps III,2005).So, the research choose the silhuate lines as the methods for analysis. The silhuate lines contains the turns of buildings and dimension of buildings .An the other hand, eliminate the elements that design by subjectivity such as texture, ornament. etc. The data of the building is come from the institution of Planning, Nanjing. (figure 6)

At every instant, there is more than the eye can see, more than the ear can hear, a setting or a view waiting to be explored (Kevin Lynch 1960). By the pattern more complexity if we want to describe the information more clearly of buildings which located in blocks internal (figure 8),we need to make more segments that like a gridding so we can cover them all(fig.9). So, how to describe the internal information of blocks it's very significant for the reseach. In this, we take the method of segment for analysis. Each of segment is been cutted aequilate . The first segment is on behalf of the streetscape, so we defined the width of segment is the longest distance between the building and street (figure 6) .And the width of other segment is decisioned by the

first one that because that the most important skyline is the first one is been perception by directly. the number of segment is decided by the shortest street one is used for pedestrians and automobile.

The formula for the number is(L is the shortest street)

$$N = \frac{\text{length of shortes street} / 2}{x1}$$

X1 = the longest distance between the frontage and street

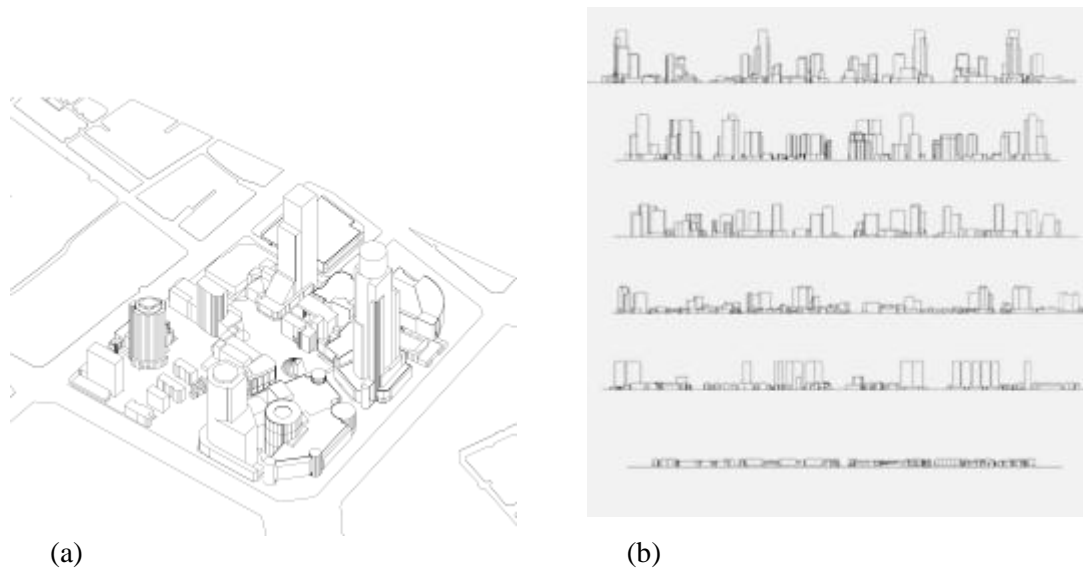

Figure 6. (a) The model of blocks; (b) Orient information of height.

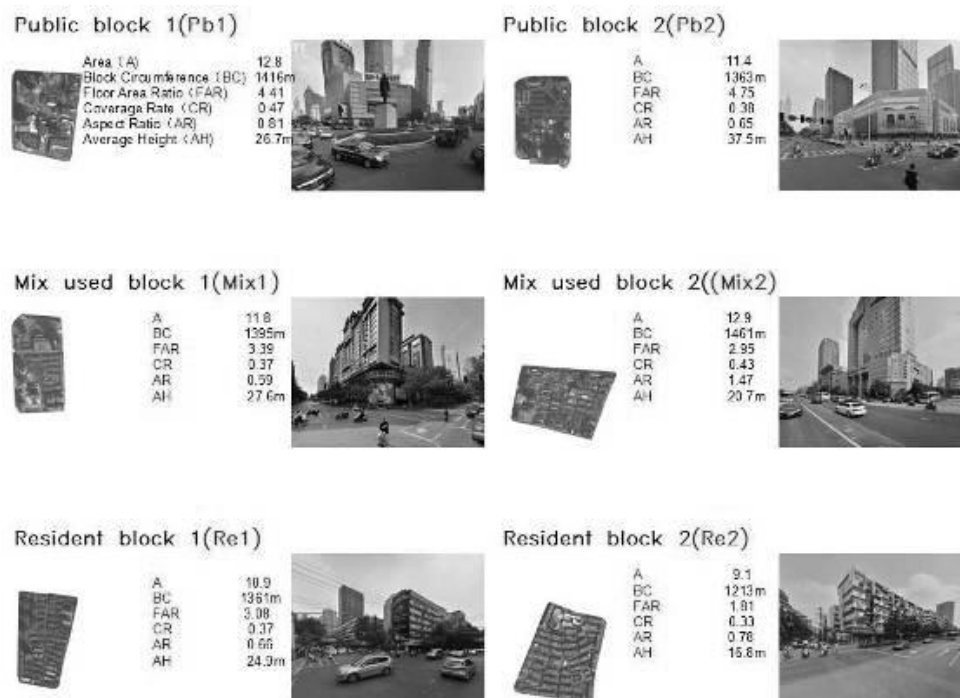

Figure 7. Six typical blocks.

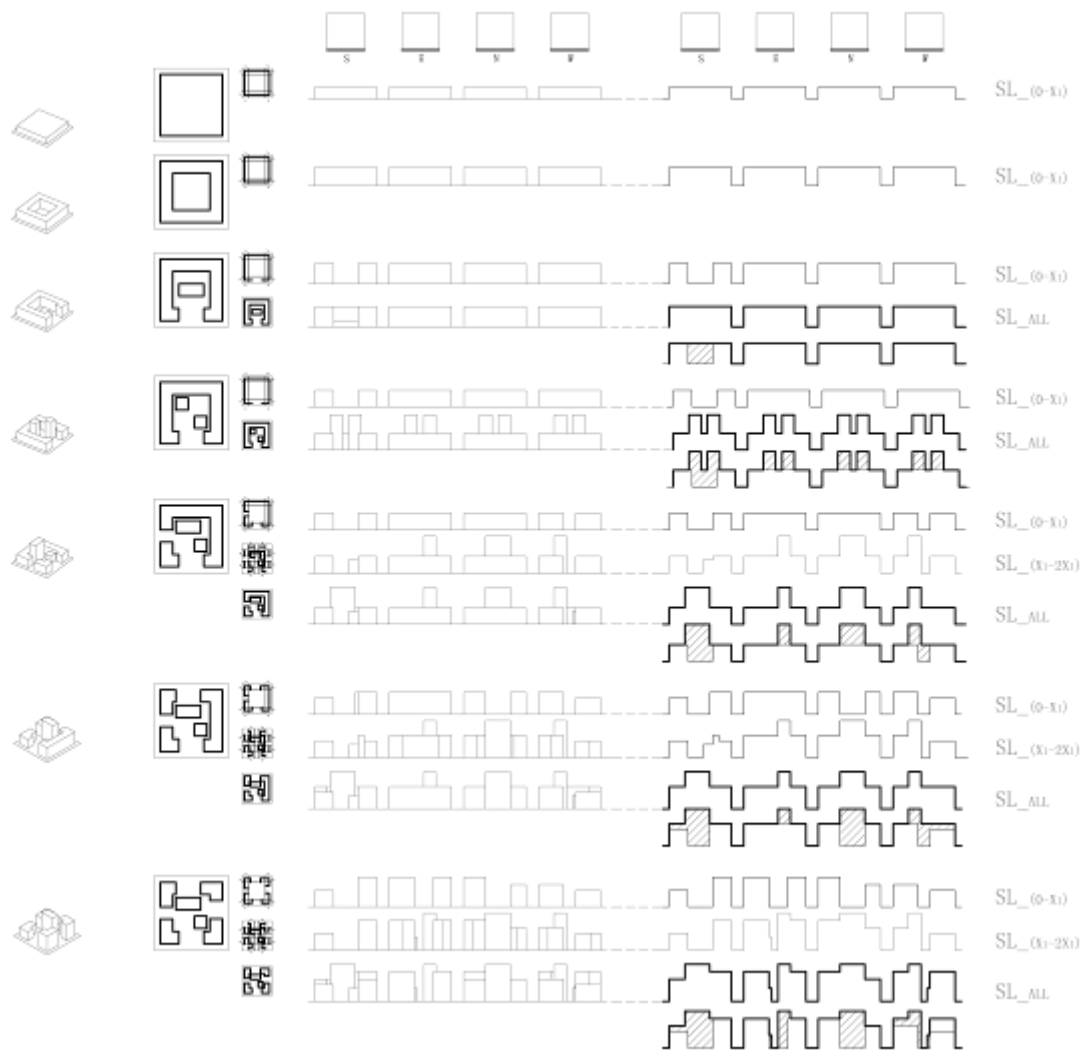

Figure 8. Pattern more complexity more segments be required.

Figure 9. Define the X1 and segments be maked.

Level 1 streetscape silhouette (x1)

This level is supposed to analysis the streetscape that influence the peoples life most directly. It is this variation within a theme that designers are seeking to replicate and to which people seem to respond positively (Jon Copper 2003). So it is significant that the designers have the knowledge of how the properties and indicator has the impacted. We calculate the distance

between the frontage and street for identify the X1 is about 30m which can cover the most of buildings facade people can observed. And the shape information is been calculate in Table 2.

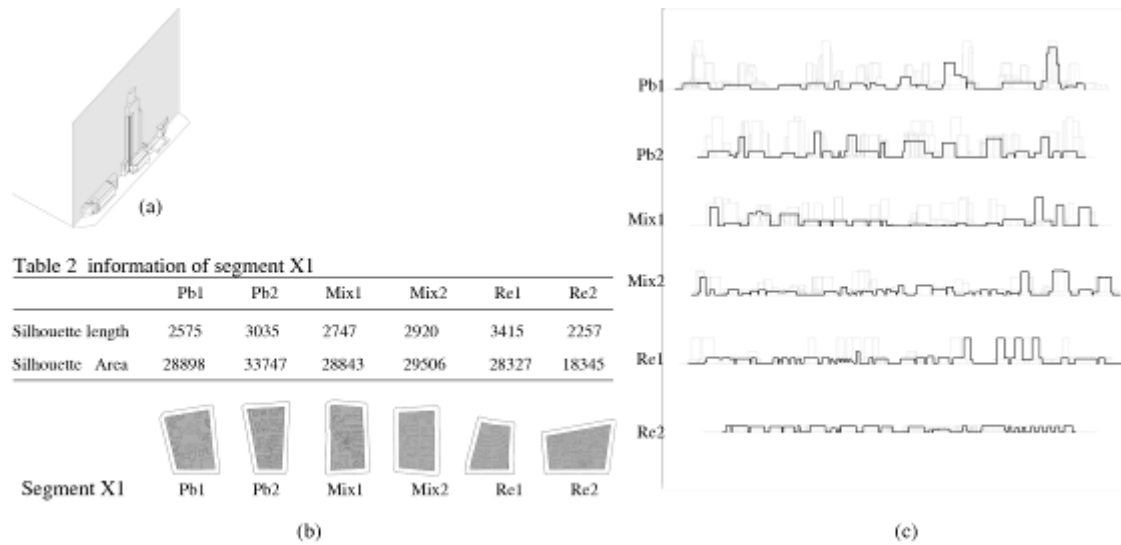

Figure 10 (a) the theoretical model that how the segmentX1 is been maked; (b)the patterns that the segment(area of grey is null); (c)The silhouette of X1.

Level 2 silhouette of different segments

To consider the CR changes of silhouette which can distinguish shape changes of interior and External. In our experience that public blocks has more shake in streetscape, it's to be concern that whether the shake is presented by the streetscape or by the changes of silhouette which located different, researching this appearance can give the planner and architecture where we choose the building located that can form the silhouette or image we hope to.

Using the formula that define the numbers of segment we calculated the N is about 5.(figure 11, figure 12, figure 13 and figure14) Then, we make five segment and statistics the length of silhouette and the area of each one.(table 3, table 4, table 5 and table6).

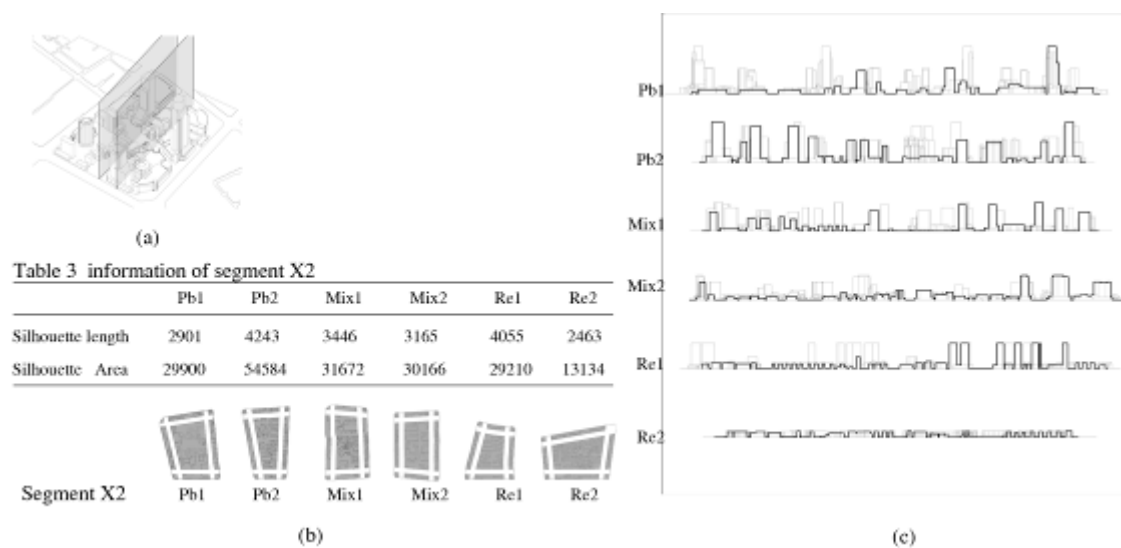

Figure 11 (a) The theoretical model that how the segmentX2 is been maked; (b) The patterns that the segment(area of grey is null); (c)The silhouette of X2.

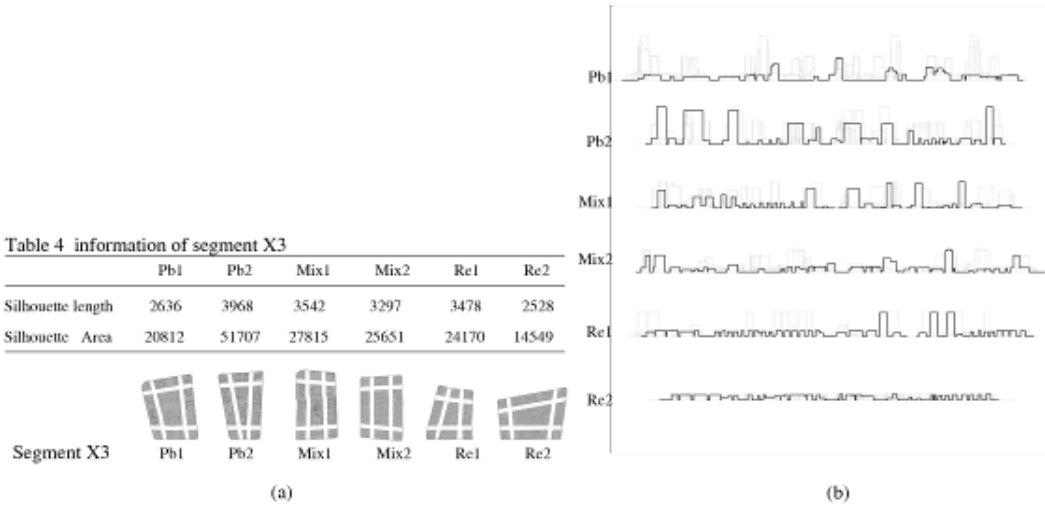

Figure 12 (a) The patterns that the segment (area of grey is null); (b) The silhouette.

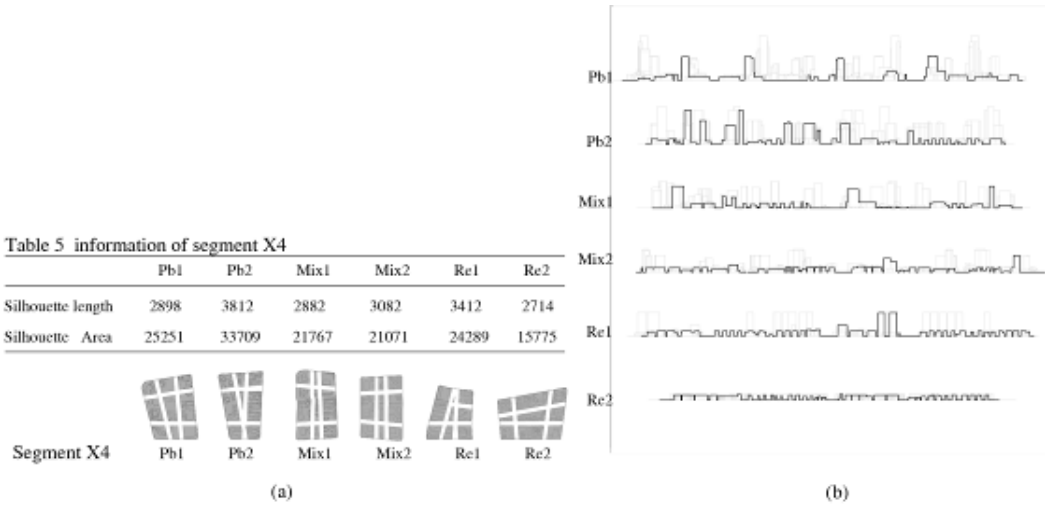

Figure 13 (a) The patterns that the segment (area of grey is null); (b) The silhouette.

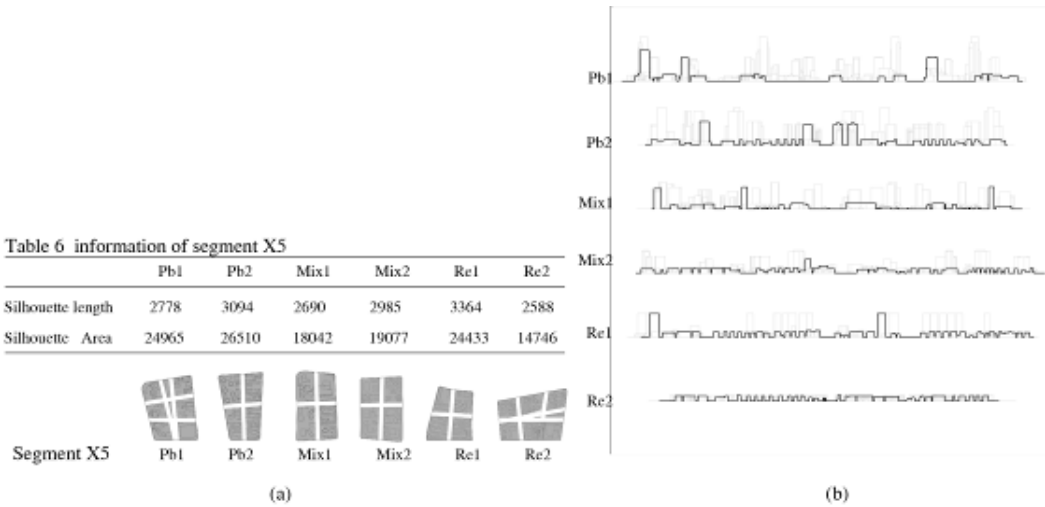

Figure 14 (a) The patterns that the segment (area of grey is null); (b)The silhouette.

Level3 silhouette of whole block

To consider the relationship of planning control index and shapes of skyline. The skyline is the contour of the sky segment in an image and its fractal dimension is regarded as an important feature which may be used to estimate natural scenes (Stephan K. C 2008). Although we didn't calculate the fractal dimension as the indicator, we can confirm that the shape of skyline has important influence on the blocks appearance.

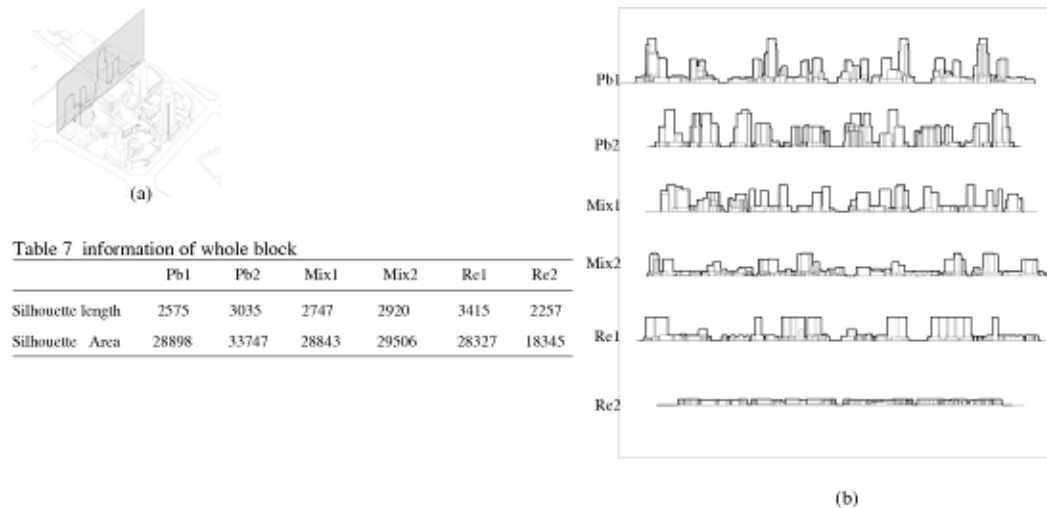

Figure 15 (a) The theoretical model that how the skyline is been described; (b) The silhouette of whole block.

Level 4 percentage of background

The Superposition Ratio (SR) of the streetscape silhouette and block skyline reflect the scope that block internal and external. By calculate the percentage of the bareness which means the whole area except superposition part we can infer to the extent of changes. We define the indicator the percentage of background (PB).

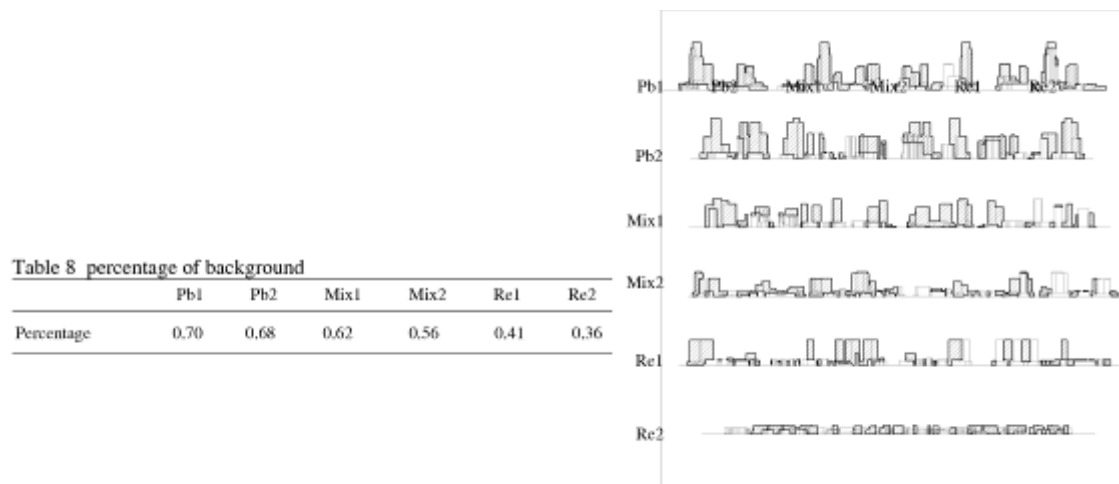

Figure 16. Percentage of background that be enclosed by the streetscape and skyline.

Discussion

Properties has influence to form

By analysis the length of silhouette & floor area ratio (FAR) (fig.17a), we found that the Resident block (Rb) has the longer length by transformation the FAR, the reason why we could calculated by that is because that the pre research have confirmed that when the coverage ratio of blocks is equal the height of silhouette in a linear fashion. The reason for that is because the plan of public buildings is bigger than resident so the equal acreage the more buildings in resident. Another reason for that may be the resident buildings a more close to the street than public buildings (buildings have to give some space close to street for enter in).

The compactness ratio of Resident blocks is lower than public buildings (figure17b) when the segment is close to the street. which can be explain that though the buildings close to the street few but each of them has big acreage so it looks more compactness, but the resident buildings has individual.

However, when we research the skyline of block we found that the president has higher compactness ratio than public one (fig.17c). It can be explain that the height of resident is almostly so we describe the skyline more smooth has the lower CR. The public one looks sharp by reason of the discrepancy of different buildings.

The percentage of background of blocks confirm that the public block has more facade bareness (figure17d), the reason is same to the compactness ratio of skyline.

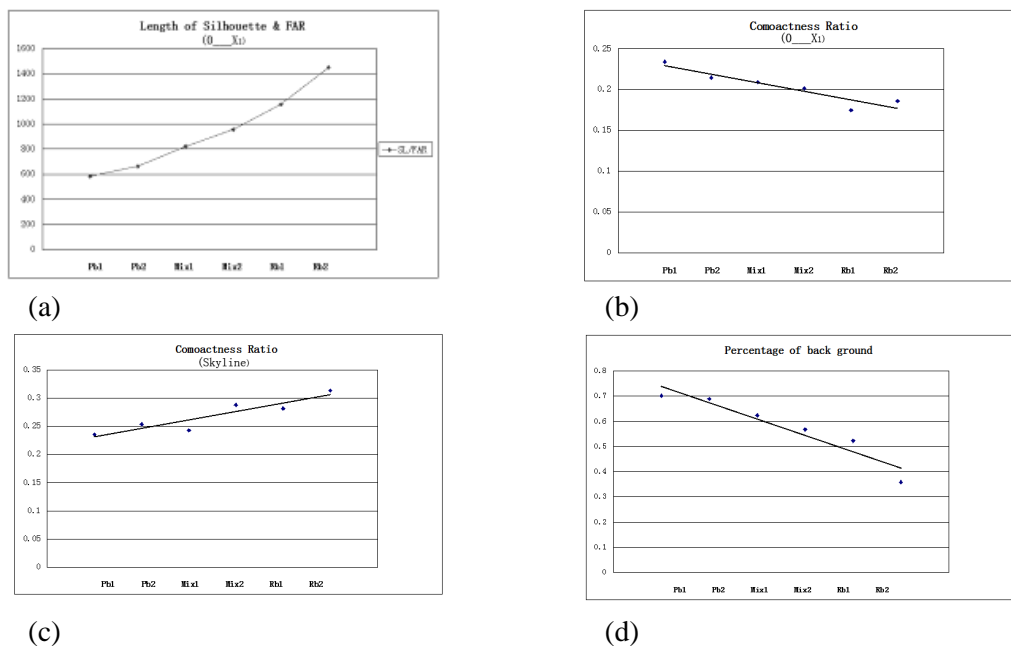

Figure 17. Relationship between silhouette shapes and properties: (a) length of silhouette & floor area ratio (FAR) _segment X1; (b) compactness ratio of silhouette and properties _ segment X1; (c) compactness ratio of silhouette and properties _ skyline; (d) percentage of background and properties.

How the silhouette shapes varichange

No matter the public blocks or the resident blocks the deeper with the area the lower compactness ratio it will be. The rate of change indicates that the public block changes more acute. The decline of CR has confirm that it's more smooth inexternal whatever the public block and resident block. But whether all the changes the public block has higher compactness ratio in the

same segment, means the public block more concentrated in external and internal.

Figure 18. The varichange of silhouette shaped in different located.

The relationship of Compactness ratio and indicator

By compare the data of Compactness Ratio (CR) and indicate, the research found some rules, and define which indicator has the direct impact the form of skylines. The previous study has confirmed that the properties of block may have an influence on shape of skyline, the research calculate the percentage of public buildings (means the area) in different blocks. The statistical results show that there has a break point when the proportion is 0.6, it means that the more public buildings the less compactness ratio the skyline has.(fig.19a) The Length/Width Ratio has the influence on pattern (MJ Barnsley,2003).

By compare the date of Compactness ratio (CR) and Length/Width Ratio the graphical representation that by the increase in Length/Width the Compactness ratio (CR) is much (figure 19b). Means that if the block shape is more pointed the skyline is more concentrate on. In our experience, if buildings are taller so the shape and the length of skyline is easier to be identify, By compare the Average Height (AH).

The figure 19c, figure 19d make clear that Compactness ratio (CR) of skyline has no clear link to the average height and the floor area ratio (FAR).

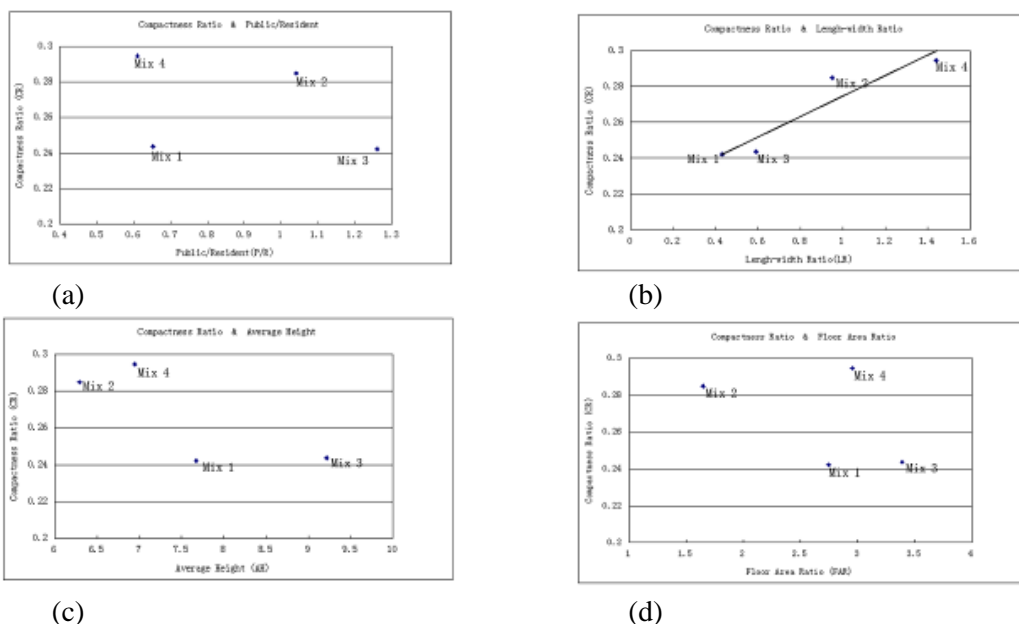

Figure 19. Relationship between silhouette shapes and indicator: (a) CR & percentage of public buildings; (b) CR & Length/width of blocks; (c) CR & AH; (d) CR & FAR.

Conclusion

The former quantitative approaches have clarified the importance of research in blocks silhouette. Then analysis the indicator for distinguish the different properties and give the main points of research .By summarize the pre research about skyline, the research discriminate some important features. Based that features research present a framework in a reasonable way .And define the rules for describe the silhouette by segment. Through compare the data which come from the segment there has some conclusion:

- i) resident block (Rb) has the longer length than Public blocks;
- ii) the compactness ratio of Resident blocks is lower than public buildings in streetscape;
- iii) the president has higher compactness ratio than public one on skyline;
- iv) the public block has more facade bareness;
- v) no matter the public blocks or the resident blocks the deeper with the area the lower compactness ratio it will be;
- vi) compactness Ratio(CR) is related to the length/width ratio of blocks.

Urban form and accessibility to rail transit stations: a case study of Auckland

Saeid Nazari Adli

School of Architecture and Planning, University of Auckland.

E-mail: saeid.nazari-adli@auckland.ac.nz.

Abstract. *Rail transport is an environmentally friendly alternative to the use of the car. People are more likely to walk to a Rail transit stations or RTS for a commuting trip than to take a car. Providing RTSs with quality pedestrian access improves urban rail ridership. However, little research has been done to explore how the characteristics of urban form along these routes that provide pedestrian access to a RTS can influence urban rail travel demand. Urban morphology in general, and the idea of urban fringe belts in particular, have been recognised as a powerful means of understanding the physical form. This study examines how urban forms in different morphological periods affect a person's decision to walk to a RTS. All 38 RTSs in Auckland, New Zealand have been grouped into three categories, based on their location and the corresponding morphological period that relates to the development of Auckland. Using GIS, a multiple regression model has been applied to each of the three categories of stations to analyse the relationship between the ridership and three planning factors of population density, land-use diversity, and pedestrian oriented design. The results show that the transit ridership in different morphological period are differently influenced by the characteristics of their urban form. The results provide policy implications for a city to improve its walkability and increase urban rail ridership. More specifically, the results will help to inform the evaluation, design and development of more walkable surroundings near RTSs. Despite the fact that the findings will be validated in Auckland, the methodological framework is expected to be applicable in different contexts.*

Key Words: *Urban form, pedestrian accessibility, rail transit station (RTS), Auckland.*

Background

Many cities around the world have concluded that roads cannot be built fast enough to keep up with rising travel demand. Different policies are being adopted to encourage drivers to use public transport and rein in automobile use. Among different modes of transit, there is a renewed interest in rail travel and rail investment. Existing literature shows that rail transport is an environmentally friendly alternative to the use of the car. People are more likely to walk to a train station for a commuting trip (Dittmar & Ohland, 2003) than to take a car.

Most transportation-focused policies that were previously effective, such as establishing new transit services or restricting the use of cars, have encountered limitations. Planners and urban managers are turning to alternative policies with more integrated planning and design that aim to provide people with better access to transit by changing urban morphology. These efforts include new urbanism, the compact city, smart-growth, transit-oriented development and urban village movements (Bean, Kearns, & Collins, 2008). However, these attempts have seen limited success. According to Dimmar (2003), “the review of the projects that are emerging reveals that many ‘transit towns’ fail to meet their objectives. Many projects end up becoming fairly traditional suburbs that are simply transit adjacent” (Dittmar & Ohland, 2003, pp. 2-3). A recent study (Chatman, 2013) of residents currently living in the proximity of train stations shows that rail access has no statistically significant effect on people's travel behaviour. Can rail really increase the transit and walk-mode share with such behaviour? Or are urban planners promising too much? An often unspoken but key component of these alternative proposals is the morphology of the urban form along access routes to a train stop.

Urban morphology can be defined as the study of the physical characteristics of towns and cities, resulting from an evolutionary process of urban activities and planning action (Gu, 2002, p. 1). Urban morphology deals with objects and their parts, their relationships and arrangements, classification, variation, formation and historical change, with reference to the built environment (Osmond, 2008, p. 41). One of most powerful theories in urban morphology to study urban form is the fringe belt concept. Put simply, studying such belts provides a comprehensive view of the spatial process of urban outward growth and internal change (Gu, 2010). A rail transit station or RTS can be studied and grouped with regards to its morphological period context. Then planning factors will be studied in each group to find out their relative effectiveness to promote rail transit system. This compound approach to the research can open a new field for application of urban morphological methods and techniques.

The City of Auckland, which is a representative of an Australasian metropolis, has the strong urban planning objective of being a more transit friendly city. Previously characterised by the successful advocacy of motorways at the expense of rail (Gunder, 2002; Mees & Dodson, 2001), Auckland is now heavily investing in improving its rail transit system by moving from diesel to electric trains (Auckland Transport, 2014a), implementing new ticketing systems (Dearnaley, 2013), and adding new lines (Dickey, 2013). The purpose of this paper is to analyse the relationship between the ridership of a RTS and morphological characteristics of its catchment area. The outcome of the research can first, provides the basis for a more integrated transport and planning policies for Auckland and other cities with an objective to consistently promote transit ridership. And second, it introduces a new methodological framework for application of the fringe belt concept.

Theories and model

The fringe belt concept

The fringe belt concept reflects the marks on the ground from the different periods of buildings cycles (Whitehand, 1988) where mostly undeveloped lands have come into being at the edge of urban areas during periods of minimal outward residential growth. These lands are heterogeneous in plan, building forms and land and building use (Gu, 2010). In this research the fringe belt concept is adopted to classify the RTS area, which determines its position in the historical development process of Auckland city.

The Planning factors of urban form

In regards to the physical characteristics of urban form that affects transit commute shares, various policies has been suggested to promote a transit town. Many scholars have indicated that the planning factors of urban form that influence transit commute share are density, land-use diversity and pedestrian oriented design of neighbourhoods around RTSs (Cervero & Kockelman, 1997; Lee & Moudon, 2006). This study does not repeat the previous studies mentioned above but instead investigates the differences in the magnitude of the impact of each of these factors based on the morphological context of a RTS catchment.

Defining the catchment area of a station or the pedshed is very important to study planning factors. A real pedshed based on the actual street network around a RTS provides more realistic results than a simple as-the-crow-flies radial buffer. There is no exact number for the walking catchment radius of a RTS, however, some literature suggest it is between 400 to 800 metres (Bernick & Cervero, 1997, p. xii and 387; Calthorpe, 1993, p. 175; Halden, McGuigan, Nisbet, & McKinnon, 2000; Kuby, Barranda, & Upchurch, 2004). In this research the pedestrian catchment was defined as 500 metre or approximately 10 minute walking distance.

Many studies have found that density affects rail ridership significantly (Kamruzzaman, Baker, Washington, & Turrell, 2014; Ratner & Goetz, 2013; Sung & Oh, 2011). The total density which is the combination of population density and jobs density can incorporate both densities in one variable. Total density represents the ratio of the total of jobs and residents to the ground area in the pedshed (Eq. 1).

$$Density_i = \sum_j \left(\sum_k \left(\left(\frac{MBPop_k}{MBRes_k} \right) \times TotalRes_{jk} \right) \right) / Area_i$$

Eq. 1

Where:

$MBPop_k$ is the population in the mesh block number k.

$MBRes_k$ is the number of residential units in the mesh block number k.

$TotalRes_{jk}$ is the number of residential units in the mesh block number k and station pedshed number j.

$Area_i$ is the area of station pedshed i.

The mixed-use index developed by Gibbs (1962) can ranges the RTSs between 0 to 1 based on their diversity of land use pattern (Eq. 2).

$$Diversity_i = 1 - \sum_j \left(\frac{LUCnt_{ij}}{TotalLUCnt_i} \right)$$

Eq. 2

Where:

$LUCnt_j$ is the count of land use type j in station pedshed number i.

$TotalLUCnt_i$ is the total number of all land use types in the station pedshed number i.

The design quality of a RTS area is a subjective matter and difficult to quantified. The space syntax's depth score provides a good measure to calculate the integration of a RTS with its surrounding environment. The depth of one space from another can be directly measured by counting the intervening number of spaces between two spaces (Bafna, 2003). In this research the design of a RTS is measured by its depth calculated by Depthmap program (Space Syntax Network, 2014).

The number of rail transit riders in a station area comes from the latest census data (Statistics New Zealand, 2013). The same proportion of residential units of each meshblock that falls in a pedshed has been selected from the total number of rail transit riders. Here the assumption is that people will walk or cycle to the nearest station (Bernick & Cervero, 1997, pp. 253-267; Dittmar & Ohland, 2003; Krizek, 2003).

$$Rider_i = \sum_j \sum_k \left(\left(\frac{MBRes_{ijk}}{TotalRes_k} \right) \times TotalRider_k \right)$$

Eq. 3

Where:

$MBRes_{ijk}$ is the number of residential units in the mesh block number k and station pedshed part number ij.

$TotalRes_j$ is the total number of residential units in the mesh block number k.

$TotalRider_k$ is the total number of people who use rail tranist in the mesh block number k.

To investigate this relationship, as multi regression model is proposed below:

$$Rider_i = a_1 Density + a_2 Diversity + a_3 Design + b$$

Eq. 4

Application and analysis

The main feature of human settlement in the Auckland region has been the development of a substantial urban area (the largest in New Zealand) in which approximately 90% of the regional population lives. This metropolitan area is located on and around the central isthmus and occupies around 10% of the regional land mass. Home to over 1.4 million people, Auckland is a vibrant centre for trade, commerce, culture and employment (Auckland Regional Council, 2010).

Data collection

Data on population density and ridership was collected from the 2013 New Zealand census (Statistics New Zealand, 2013). The data on land-use diversity was collected from the Auckland council GIS viewer website (Auckland City Council, 2013). The data for parcel area is collected from the university library GeoDataHub (University of Auckland library, 2013). Other data used in this paper are meshblock boundaries (Statistics New Zealand, 2013), street network (Open Street Map, 2014), rail station location and rail transit network (Auckland Transport, 2014b) (Figure 1).

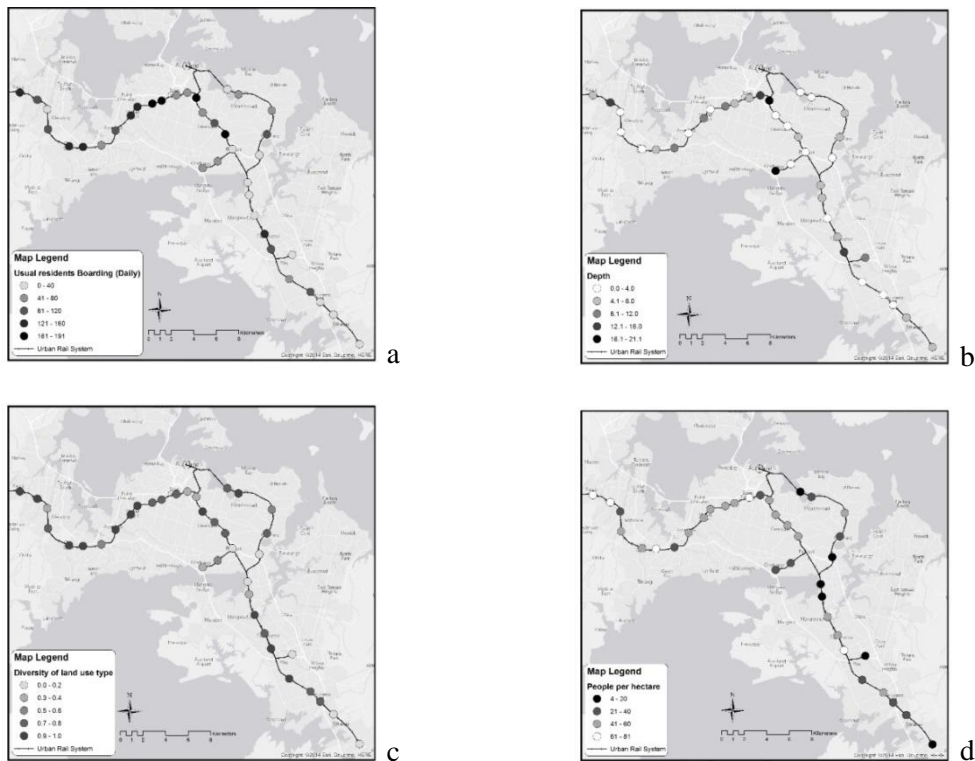

Figure 1. Daily riders (a), the planning factors of the station areas (b–d).

Catchment

Open street map or OSM is a free knowledge collective that provides user-generated street maps. In this research, the ArcGIS 10.2 was used to download and model street network from Open Street Map website (Open Street Map, 2014). ArcGIS Network Analyst is a powerful tool that can generate a realistic walk mode service area for a location based on a street network. Using the Network Analyst, the transit station pedsheds was drawn based on OSM data (Figure 2).

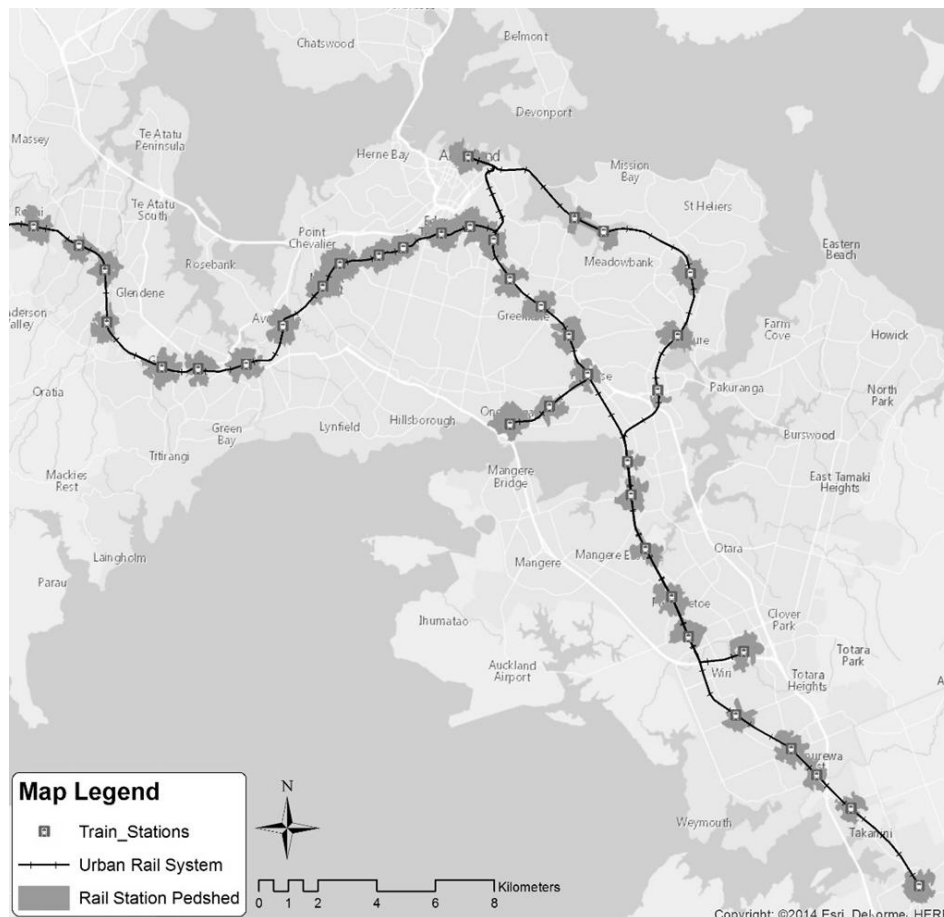

Figure 2. The rail transit station pedsheds of Auckland metropolitan area.

Clustering the station areas and the fringe belt concept

The morphological periods of Auckland investigated by Gu (2010) have been used as the basis for clustering rail transit stations based on their morphological context. Gu (2010) has determined four morphological periods of expansion of Auckland isthmus: pioneer development (1840-1880), Late Victorian and Edwardian (1890s-1900s), The interwar (1920s-1938s) and early post-war (1950s-1960s). Characterised by “distinctive planning ideologies that have left observable material residues”. These characteristics are summarized in Figure 4.

A series of concentric fringe belts can be recognized at the edge of each morphological period. The inner fringe belt surround the kernel of the city. A discontinuous middle fringe belt marks the edge of the late Victorian and Edwardian growth, and an outer fringe belt marks the edge of the interwar development (Gu, 2010) (Figures 3 and 4).

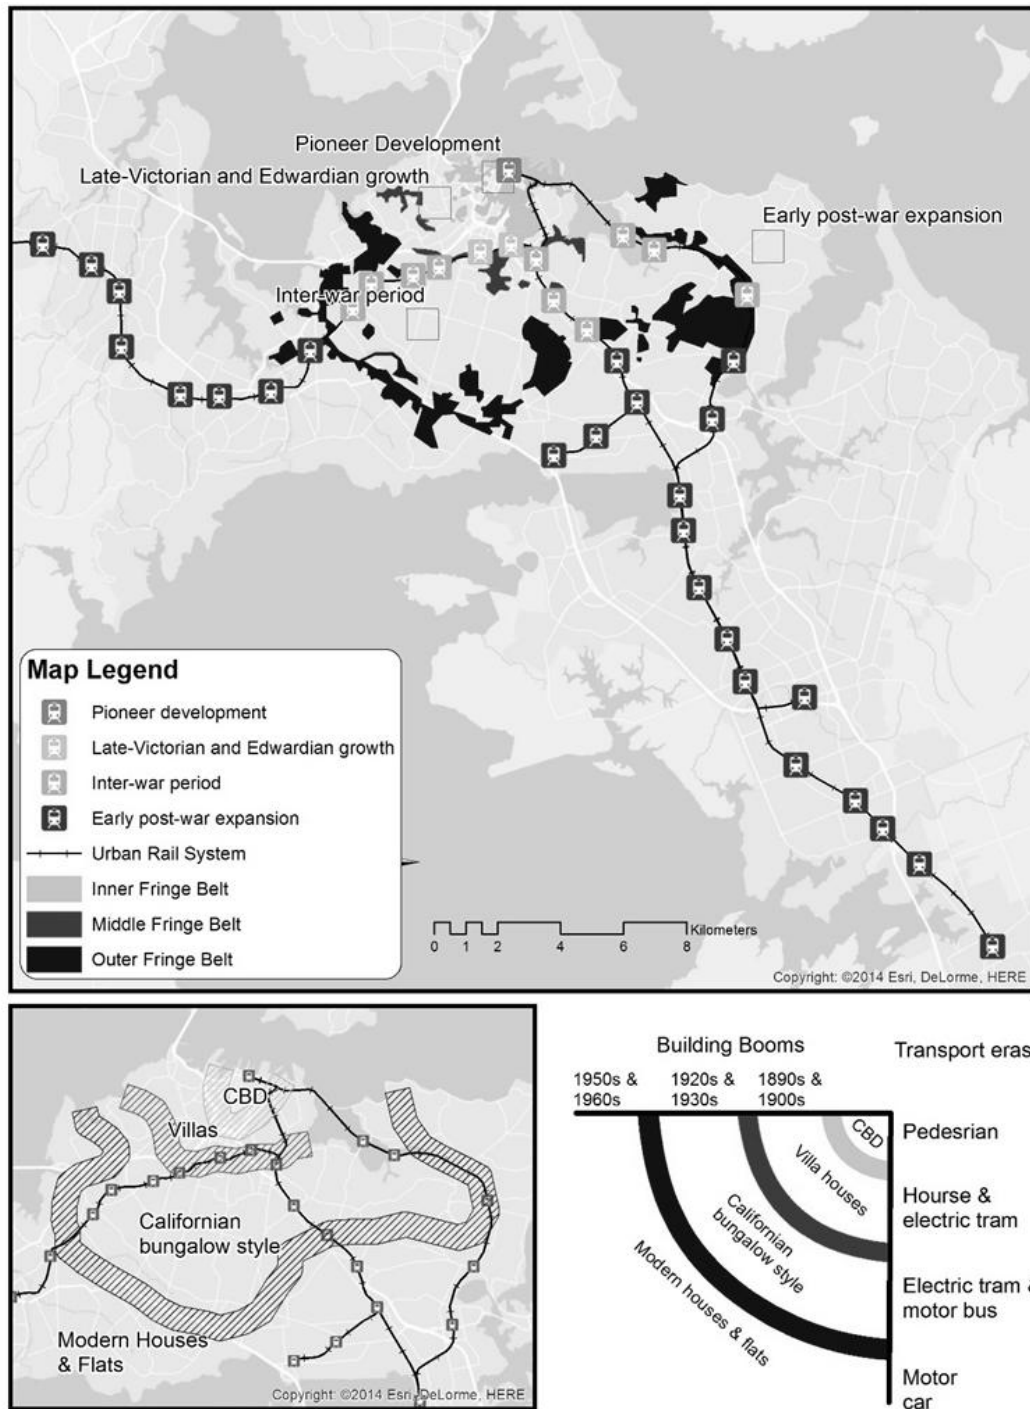

Figure 3. Auckland fringe belts and clusters of rail transit stations (Gu, 2010).

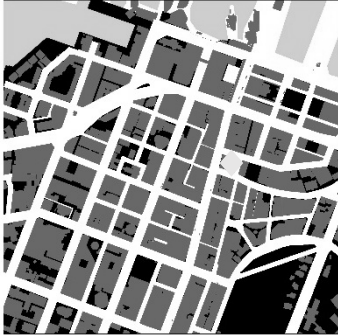

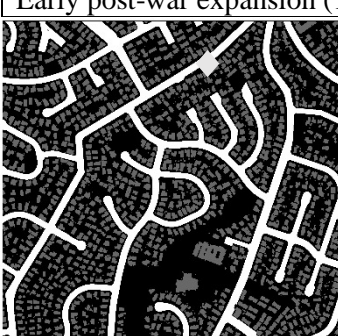

Pioneer development		
		<ul style="list-style-type: none"> -The kernel of the city, now the CBD -geometrical pattern Winding streets mainly follow the coastline
Late-Victorian and Edwardian growth (1890s-1900s)		
		<ul style="list-style-type: none"> -Characterised by the construction of streets meeting at right angles. -Back-to-back plot pattern relatively high-density built environment -Single-storey-detached villas
Inter-war period (1920s-1930s)		
		<ul style="list-style-type: none"> -A grid street pattern reflecting the influence of garden suburb ideas -Californian bungalow and mission styles
Early post-war expansion (1950s-1960s)		
		<ul style="list-style-type: none"> -Loop roads, crescents, culs-de-sac and irregular shapes -Building types of this era were characterised by rectangular shapes, concrete block walls, split levels and flat roofs

Figure 4. Ground plans and building types representing the morphological periods (Gu, 2010).

Results and discussion

Multiple ordinary least squares regressions has been employed to analyse the effects of the hypothesized independent variable on RTS's ridership. Multiple regressions is very flexible to use and easy to understand, however, similar to all statistical tools the results is highly dependent on the sample size. The pioneer development of Auckland city host only the Britomart station and there are only two stations between inner and middle fringe belts (Figure 3). Thus, these stations has been excluded from the analysis.

The research focuses only on inter-war and post war developments and compares the results to the whole city. For this purpose three different regression model for inter-war area RTSs, post-war area RTSs and the whole city RTSs calculated to indicate the magnitude of the coefficients of planning factors in each of these areas. All regression models were statistically significant and had an appropriate goodness of fit. The results of the model estimation are summarized in figure 5.

Application	N	Parameter	Standardized Coefficients	R ²	Adj. R ²	F-Value (sig.)
The whole city	36	b	-43.04	.500	.453	10.668(.000)
		Total Density	.319			
		LU Diversity	.566			
		Depth	.275			
Inter-war development	10	b	-120.00	.627	.441	3.368(0.096)
		Total Density	.626			
		LU Diversity	.511			
		Depth	.420			
Post-war development	26	b	-16.03	.481	.410	6.786(0.002)
		Total Density	.174			
		LU Diversity	.650			
		Depth	.099			

Figure 5. Summary of regression analysis.

The comparison between results of regressions indicates verifies this assumption that planning factors are highly contextual and they vary depending on characterises of each morphological period of development. The regression analysis of boarding and planning factors on the whole city (Eq. 5) indicates the coefficient of land-use diversity was largest and that of density was larger than that of design. Same pattern could be seen post-war developments (Eq. 6) however with larger difference between diversity and the other two factors. This trend changes over the inter-war period area of development as the density is more important than diversity and design (Eq. 7).

$$\text{Eq. 5} \quad \text{The whole city : } \text{Rider}_i = .319\text{Density} + .566\text{Diversity} + .275\text{Design} + b$$

$$\text{Eq. 6} \quad \text{The post – war: } \text{Rider}_i = .099\text{Density} + .650\text{Diversity} + .099\text{Design} + b$$

$$\text{Eq. 7} \quad \text{The inter – war: } \text{Rider}_i = .626\text{Density} + .511\text{Diversity} + .420\text{Design} + b$$

Figure 6. Standard coefficients.

The interest toward public transport have recently developed in many cities around the world. The general idea of developing a dense, pedestrian friendly, mixed use urban fabric around rail stations is common in strategic growth plans for cities. This research assumed, even though the planning factors are influencing the ridership, this influence is different based on the characteristics of urban fabric.

Urban morphology provides a powerful conceptual frame work to identify homogenous urban fabrics based on the ideology that produced it. Urban morphology has been successfully developed in several areas of planning and design practice, notably urban conservation, urban design, and urban coding and planning (Gu, 2013) but it has not been incorporated in integrated planning and transportation policies yet. The purpose of this research was to analyse the relationship between ridership and the aforementioned planning factors to verify that morphological study of urban fabric can play an important role in new trends in transportation policies.

The results indicate that each morphological periods of development have different priorities to make a city more transit friendly. The periphery areas of post-war development are influenced mostly by diversity, whereas riders in the inter-war development areas are affected mainly by density. Consequently clustering RTSs based on their morphological characteristics is a useful way to establish proper land-use plan and increase their ridership. These findings support the research assumption that each RTS pedshed should be planned differently based on its morphological characteristics.

Systems thinking for new perspectives on urban form – a case study of active transport infrastructure in urban corridors

Nicholas Stevens¹, Paul Salmon², Natalie Taylor²

Abstract. *Urban planning and design require new ways of interpreting urban form that allows for the understanding of multidisciplinary approaches and cooperative outcomes. This innovative study brings together the disciplines of Human Factors with Urban Design to investigate the form and design of active transport infrastructure (ATI) in urban transport corridors (Stevens and Buksh, 2013). These connectors of people and place go beyond the roadway and consider the dynamics of adjacent urban form. They are defined by the disparate demands of engineering, urban planning, urban design, property development and community expectation. Using Cognitive Work Analysis (CWA) this study investigates and identifies the interdependencies and ability of these urban corridors to operationalize ATI which permits best practice road user hierarchies that give highest priority to walking and cycling. CWA (Vicente, 1999) is a systems analysis and design framework that identifies the constraints imposed on activities and designs new systems that better support the activities of interest. CWA has been used in a variety of design activities in several domains, including defence, disaster management, process control, and road safety (Salmon et al., 2010). This research is the first to apply CWA as a tool to interpret the interdependencies of urban form and its component elements. The application and extension of sociotechnical systems theory in an urban setting has allowed for unique insights. A key aspect of the framework is that it is formative in nature describing what could happen if design modifications are undertaken, rather than provide normative analyses of what should happen. The results of this study allow for a clearer interpretation of the relationships between all of the physical elements of ATI and its intended functional purposes. Through the analysis of ATI this research provides a means to understand the multidisciplinary requirements for establishing urban form which supports safe and accessible use by pedestrians and cyclists.*

Key Words: *Cognitive Work Analysis; Urban Corridors; Systems Analysis; Multidisciplinary Design Framework, Active Transport Infrastructure*

Introduction

This paper proposes that the urban form of our cities needs to be underpinned by a better understanding and prioritisation of community access. This paper seeks to offer insights into the design of streets which are prioritised as key community conduits and destinations in their own right. It outlines a systems approach which enables multi-disciplinary responses to the establishment of active transport infrastructure (ATI) which supports and encourages pedestrians and cyclists within the urban corridor.

Public space within cities is a dwindling resource, yet though appropriate design, or indeed redesign, our footpaths and roadways have the capacity to host community life. They offer the greatest opportunity and potential for our neighbourhoods and urban environments to act as social places. The role that streets and footpaths should play in contributing to quality of life is firmly entrenched in urban design and urban planning theory (Lynch, 1960; Jacobs, 1961; Appleyard, 1980; Gehl, 2011).

There is a range of literature, plans and strategies that outline the known benefits of active transport, including, reducing vehicular congestion, greenhouse gas emissions and supporting

individual and community health (Woodcock et al., 2007; Frank et al., 2010; SCRC, 2011b; Millward et al., 2013). This research instead focuses on the design and form of active transport infrastructure. Specifically it is concerned with the provision of pedestrian footpaths and on-road cycling facilities within existing urban roadway contexts. Many of these roadways were never designed or intended to provide for active modes of transport and subsequently often do not support safe interactions between different road user groups.

This 'systems thinking' approach to road design is a key requirement for future road systems (Salmon et al., 2012). It is able to consider the relationships between the ideal functional purposes of active transport infrastructure and highlight the system relationships. While the urban form and roadway contexts are key inputs into the system, the approach specifically identifies the range of interdependencies between functions, purposes, and objects within a typical active transport infrastructure configuration.

The literature on active transport emerges from a range of discipline areas including health promotion and preventative medicine (Frank et al., 2010; Hamer and Chida, 2008); transport geography (Kelly et al. 2011, Millward et al., 2013); and urban planning and design (Forsyth et al., 2007; 2008; Ewing and Cervero, 2010). This research provides new knowledge through the convergence of the Human Factors and Urban Design disciplines.

Significance and research challenges

The potential of roadways and more specifically existing urban corridors to act as community and neighbourhood places support by active mobility is recognised in literature, planning and policy (IPWEA, 2010; SCRC, 2011b; Stevens and Buksh, 2013). Additionally, there are a variety of evaluative techniques that seek to establish and reprioritise active transport, and the amenity to support it, through principles of urban design and health promotion (Cerin et al., 2007; Clifton et al., 2007; Ewing and Handy, 2009; Millward et al., 2013). While much has been done to better understand and evaluate the contributions of built form and community life which encourages active transport there is also a continued acknowledgement that implementation of appropriate strategies needs to be improved (Stevens and Buksh 2013). This research recognises three main challenges that have inhibited the ability of urban corridors to be significant locations of active mobility.

First, is that past and present design standards for roadway corridors prioritise motor vehicles over all other uses (P and NJ, 2008; TMR, 2013). The engineering based standards are largely not concerned with the delivery of quality urban design or form, but the efficient and safe movement of motorised traffic. As transport agencies increasingly seek to enable active mobility, the supplied active transport infrastructures are required to be established within an existing roadway context. Footpaths and on-road cycleways are required to 'fit' within the roadway corridor without specific consideration of the needs of active mobility. This post hoc delivery of painted on-road cycle markings and standard concrete footpaths may fulfil departmental and agency policy for implementation, but they are not fit for purpose.

Second, is that the engineering or urban design guidance which does seek to enable walkable and cyclable neighbourhoods is very rarely considered in an integrated manner. The engineering standards are not interested in ensuring visual amenity and sense of place, and the normative principles of urban design are often difficult to apply in practice. That is, much of the urban design guidance for active transport infrastructure is often descriptive or illustrative (ITE, 2010; IPWEA, 2010). The provision of key principles and listed objectives of primary considerations; supported by illustrations and elevations of what should be done, may be argued to limit the in-practice uptake of such advice (Stevens and Buksh, 2012).

Third, current active transport 'solutions' rarely seek to exemplify safe, efficient or best practice sustainable transport, nor do they support a high quality active transport user experience. As such, despite implementation of ATI, increases in activity are often limited (Alfonzo, 2005; Paige Willis et al., 2013). Further, there is very little evidence that such

infrastructure considers the implications or interactions between active transport modes which are often also incompatible - pedestrians and cyclists.

The safety of active transport users continues to represent a significant issue, both in Australia and worldwide. Of the 1303 crash-related fatalities occurring in Australia during 2012, 174 were pedestrians and 33 were cyclists (BITRE, 2013). The challenge is how to retrofit urban corridors which are safely engineered for active transport and establish urban form which encourages use through contributions such as amenity and sense of place. The identification of design frameworks that can support the development of appropriate active transport infrastructures which prioritise walking and cycling is critical.

The application of systems analysis and design approaches for roadway configuration and evaluation is gaining momentum (Salmon et al., 2014; Cornelissen et al., 2013). This research argues that the Cognitive Work Analysis framework (CWA; Vicente, 1999) provides a suitable design approach for active transport infrastructure within the urban corridor. The aim is to show how CWA can contribute to the design of safe and efficient active transport environments which provide a high quality user experience. This paper outlines an approach whereby it is possible to better understand the role and interactions of active transport infrastructure within the urban corridor. The aim is to provide a single analysis with the potential to consider both the engineering and technical standards of safe active transport infrastructure with the urban design opportunities and experiential contributions as high quality places for walking and cycling. Much of the current literature and policy seeks to deal with these issues independently, or in turn, here they are considered as interdependent.

The study described uses the first phase of the CWA framework, Work Domain Analysis (WDA) to model the 'ideal' active transport infrastructure configuration, considering the current practices of retrofitting existing urban corridors.

Urban corridors

The idea of the urban corridor is not new and has historically been used to describe the growth and development between key activity centres (Sargeant et al., 2009). Indeed the concept of the urban corridor has been used as a spatial planning unit of analysis in several national and international investigations (OA, 2010; Aust. Gov, 2007; Government of South Australia, 2011).

These transport focussed corridors, within an urban environment, are naturally complex as they transverse across different scales and are influenced by a collection of economic, environmental and social relationships connecting people and place. Hale (2011) and Arrington and Cevero (2008) identify the need to carry out corridor analysis at different scales to better understand how a particular transport initiative, corridor upgrade, or Transport Orientated Development (TOD) proposal relates to the broader urban setting.

Hale (2011) argues that this is a practical step forward and must be carried through the development of analytical tools, ultimately leading towards better outcomes for projects at different spatial scales over time. Urban corridors of any scale or function and their surrounding urban catchment have reciprocal latent and explicit impacts which require further investigation, understanding and management (Stevens and Buksh, 2013).

For the purposes of this paper the *urban corridor* represents a 400m buffer along road based transport corridors, often containing public transport (Adams, 2009). These urban corridors are key development areas and community conduits which respond to and consider adjacent site, local and corridor urban context.

Cognitive Work Analysis and Work Domain Analysis

The CWA framework is concerned with constraints rather than goals, and is based on the notion that making constraints explicit can potentially enhance human performance. To identify and understand these constraints the CWA framework comprises five interrelated phases, this research involved applying the first phase, Work Domain Analysis (WDA).

WDA is used to describe or model the system of focus by describing the purposive and physical constraints imposed on activity within a particular system. This involves constructing an Abstraction Hierarchy (AH) of the system in question. The AH represents the system across the following five levels of abstraction (Naikar et al., 2005):

Functional purpose – The overall purpose(s) of the system and the external constraints on its operation;

Values and priority measures – The criteria that the system uses for measuring progress towards its functional purpose;

Generalised functions – The general functions of the work system that are necessary for achieving the functional purposes;

Physical functions – The functional capabilities and limitations of the physical objects within the system that enable the generalised functions; and

Physical objects – the physical objects within the system that afford the physical functions.

The output provides a constraints-based model of the system which describes the purposes, values and priorities of the system, the functions that are performed within the system and the physical resources that are used to perform the required functions. WDA addresses what activities can be performed within a particular system, but also how and why they are performed and with what. This paper asserts that these characteristics make it highly suited to inform the design of active transport infrastructure that both incorporates safety and sense of place, since it is capable of describing what design features are required, and what values and priorities should be met through the design.

The CWA framework has been applied in various areas for systems analysis and design applications (Bisantz et al., 2003; Cornelissen et al., 2013; Jenkins et al., 2009; 2010; Naikar et al., 2003; Naikar and Sanderson, 2001; Watson and Sanderson, 2007); however, it has had only limited application in the consideration of urban design contexts (Stevens and Salmon, 2014). In this study, the WDA was used to create a model of an ‘ideal’ active transport infrastructure configuration, which considers the need to retrofit existing urban corridors.

Methodology

Work domain analysis (WDA)

The development of the WDA was based on key design guidelines and standards, best practice documentation and the literature on urban design, active transport, and on-road cycleway and footpath engineering (See Table 1). This data represents national standards for footpath, pathway and cycleway design; national and international engineering design guidance; and governmental active transport and urban design policy and protocol. It is indicative of the range of active transport design guidance from across the often disparate disciplines of engineering, transport planning and urban design. Based on these inputs the WDA was developed by one Human Factors analyst and one Urban Planning practitioner.

Active transport and urban design literature

The WDA has also drawn on a range of urban design and active transport literature to allow for the establishment of high quality active transport user experiences. It is important to note that the concepts described here also emerge across a range of practice and academic literatures and

are by no means exhaustive on the topic of active transport infrastructures or the operationalization of urban design principles or subjective qualities. Concepts within this study represent those which respond largely to the context of policy and practice in South East Queensland and Australia more generally (Aust Gov, 2011; SCRC, 2011; PIA, 2010). Additionally there has been the inclusion of key elements and considerations that have emerged within the literature, planning and policy relating to: walkability and active transport (Purciel and Marrone, 2006; Ewing and Handy, 2009; Ewing and Cervero, 2010; Millward et al., 2013); urban thoroughfares and corridors (Premius and Zonneveld, 2003; ITE, 2010; Stevens and Buksh, 2012); pathway and cycleway design guidelines (Austroads, 2009; WSDoT, 2011); user orientated spaces (Yücel, 2013); and quality human environments (Gehl, 2011).

Urban context of the active transport infrastructure WDA

When considering the urban design and the engineering requirements of active transport infrastructure within urban corridors it is necessary to acknowledge and understand the context within which they occur (Premius and Zonneveld, 2003; Stevens and Buksh, 2012). First, it is important to identify the transport task and roadway context (for example, highway, arterial

road, local road etc.). Second, is understanding the type of neighbourhood within which they occur (rural, sub-urban, urban centre, CBD, etc.) and third, is the context of the adjacent built environment within the corridor (residential, commercial, retail, open space, etc.).

Active transport infrastructure may be found in many urban roadway, neighbourhood and built environment circumstances. However the interdependency and influence of these three contexts has significant implications for both their physical design and also the quality of the user experience. For example pedestrians and cyclists have no role to play in the context of major highways, but may be expected to be key contributors to the success and vibrancy of inner city streets.

It is important to note that the WDA is actor independent and does not explore the behaviour of different users of the system. As such the WDA includes all objects that may be important to some users and of no consequence to others, for example tactile surface indicators or bike racks. The system view as represented by the WDA considers that the constraints within it are the same for all users.

Roadway context for active transport infrastructure

This research is principally interested in urban corridors that contain higher order roads that are administered and managed by state governments. As such it has utilised the urban corridor and roadway context established by Stevens and Salmon (2014) which considered the influence of 'multi-modal urban arterial roads' and 'community boulevards'. These roadway types are two of the categories established under the functional hierarchy of strategic roads as defined by the Queensland Department of Transport and Main Roads (TMR, 2009). This functional hierarchy of strategic roads identifies four (4) categories (p66):

1. high capacity, high speed motorways and highways to move large volumes of traffic, including freight traffic, over longer distances;
2. multi-modal urban arterial roads to provide connections within communities and cater for a range of road users, including pedestrians, cyclists, public transport, private vehicles, as well as commercial delivery vehicles ('first and last mile' freight);
3. bypass and ring roads to remove traffic from activity centres; and
4. community boulevards to provide amenity through activity and town centres, designed to cater for low volumes of traffic, with priority given to pedestrians, cyclists and public transport.

Neighbourhood context for active transport infrastructure

This study utilises the *South East Queensland Place Model* for the classification of the physical form and character of the neighbourhood context (CM-SEQ, 2011; Stevens and Salmon (2014). This model suggests that settlements in South East Queensland (SEQ) can be understood as a series of place types, each with common characteristics, similar land use mixes and intensities of development. The model represents what may traditionally be recognised as transect planning (Duany and Talen, 2002). The SEQ Place Model (CM-SEQ, 2011 p 62) identifies seven (7) categories of overlapping place type (Figure 1):

- P1. Natural Places – Areas dominated by the natural environment.
- P2. Rural Places – Rural production and landscapes, rural living.
- P3. Rural Townships – The range of smaller rural townships in SEQ.
- P4. Next Generations Suburban Neighbourhoods – Walkable local areas, which are people (rather than car) focussed and contain a choice of housing types and some other local uses in a mixed use setting.
- P5. Urban Neighbourhoods – Walkable, high density local areas, which are people focussed and contain a wider choice of other housing types more mixed use than suburban neighbourhoods.

P6. Centres of Activity – Vibrant and intense mixed use centres including housing, retail, employment, education and entertainment facilities. Some taller buildings are part of the built form character.

P7. CBDs – Central business districts – centres of production as well as consumption.

For this research the place types within which the active transport infrastructure WDA have been established as P5 Urban Neighbourhoods and P6 Centres of Activity.

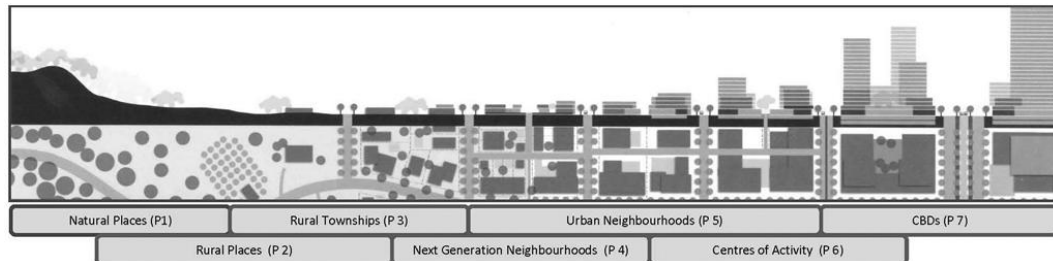

Figure 1. SEQ Place Model (CM-SEQ 2011 p62).

WDA active transport infrastructure context

The formative model developed through the WDA represents active transport infrastructure located on an urban arterial or community boulevard within an urban neighbourhood or centre of activity which has an adjacent built form context comprised of mixed use commercial, retail and residential uses. The unit of analysis is an urban block, corner to corner of approximately 150 metres in length, and 10 metres in width, begins at the building line and traverses the footpath and on-road cycleway to the roadway (Figure 2). The configuration for on-road cycling is described as a ‘wide parking lane with bicycle provision’ as it is the most commonly delivered by state agencies in South East Queensland (QG, 2013 p 9-17). The WDA considers the functions, purposes and objects within this system of active transport infrastructure.

Figure 2. Active transport infrastructure WDA unit of analysis.

Active transport infrastructure zones

As an organising device this research extends the recognised zones of a footpath (Austroads, 2009; ITE, 2010) to include the on-road cycleway and the roadway edge. The amount of space allocated to these five (5) zones and the objects located within them has a significant influence on the functions of active transport infrastructure. The identified zones may be defined as:

1. On-road Cycleway Zone: This is the distance from the edge of the motorised vehicular travel way to the kerb. It often contains provision for car parking, in addition to the markings required to indicate this space as a cycleway.
2. Edge / Kerb Zone: This area is from the face of the kerb and defines the limit of the pedestrian area. It provides the minimum separation between the objects in the footpath and other vehicles in the roadway.

3. Furnishings Zone: This zone provides the major buffer between vehicles and pedestrians. It often contains signal poles, seats, landscaping, streets trees, parking meters and so forth.

4. Throughway Zone: This is the walking zone and the area through which pedestrian usually travel. It is an area that must remain clear and be free of obstructions at all times.

5. Frontage Zone: This is the distance from the throughway to the frontage of adjacent property. It is an area which should buffer pedestrians from window shoppers and private business or residential doorway traffic. This zone often contains private street and dining furniture, merchandise displays, private signage, fences and so forth.

The WDA seeks to better understand each of these distinct zones, the relationships between them and the objects they contain. To assist in the analysis of the active transport infrastructure, where appropriate, the physical objects layer within the WDA has been arranged so as to highlight their placement within the zones.

Results

The system represented by the WDA has been summarised in Figure 3. While the *Functional Purposes* and the *Value and Priority Measures* levels of the WDA are presented in their entirety, for efficiency the nodes contained within the *Purpose Related Functions*, *Object Related Processes*, and the *Physical Objects* levels have been grouped into representative categories.

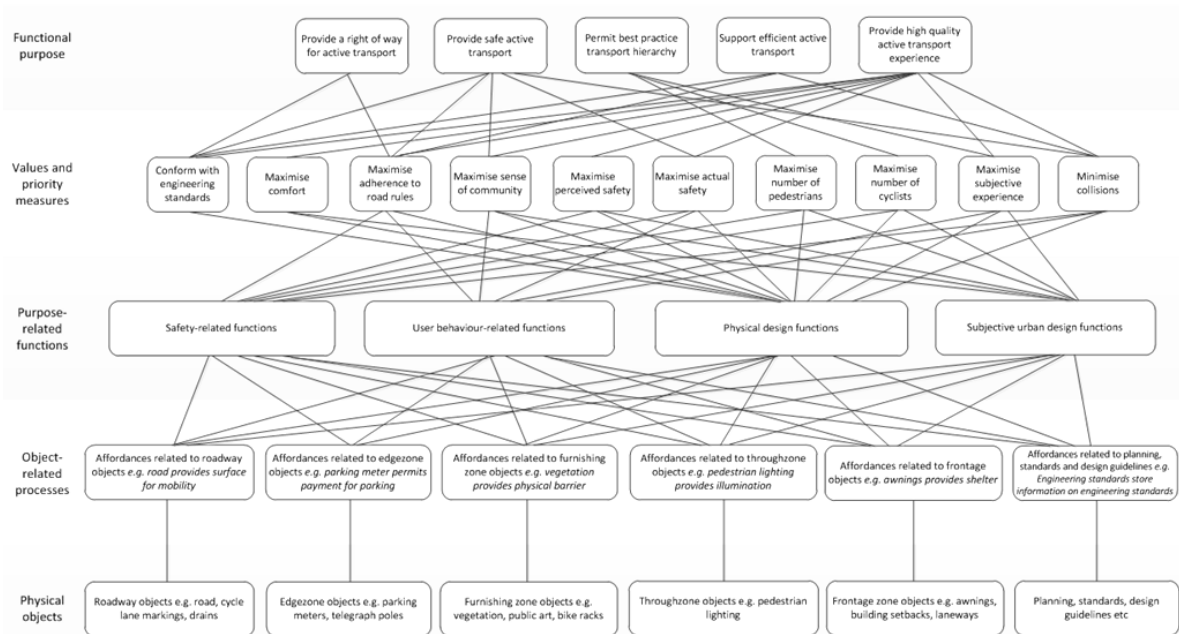

Figure 3. Summarised Work Domain Analysis.

The following discussion does not endeavour to outline all of the relationships; rather we provide an overview of the interactions between the levels of the abstraction hierarchy to demonstrate the applicability and usefulness of this method.

Functional purpose

This highest level of the abstraction hierarchy contains the reasons for the existence of the system. When considering ATI, the WDA was required to include both objective and subjective functional purposes. For example the objective purposes of the ATI to 'provide a right of way

for active transport', 'provide safe active transport', and 'support efficient active transport', in balance with the best practice and user orientated functions of 'permit best practice transport hierarchy' and 'provide high quality active transport experience'.

If the analysis had been undertaken simply by considering the function of ATI as 'provide a right of way for active transport' and 'support efficient active transport', the WDA would have yielded a systems view of how ATI is currently implemented – to accommodate these functions within the roadway corridor. Through the inclusion and analysis of the potential functions of ATI, in line with best practice, safety and user experience, the research brings together a means to understand the interfaces and possible outcomes for achieving sustainable active transport.

The important and complex relationships and interdependencies between these functional purposes are established when considering the below levels of values and priority measures; purpose related functions; physical affordances; and physical objects. It is interesting to note that the five functional purposes described at this level may not necessarily be compatible; that is, it is questionable whether ATI designs can fulfil these purposes without some trade-offs.

Values and priority measures

Values and priority measures are positioned on the second level of the WDA and outlines the criteria against which to evaluate the achievement of the systems functional purposes. That is, do these inclusions provide an indication of how the functional purposes are being achieved? For example, in this ATI system 'maximise comfort' is an important value and priority measure for the delivery of 'high quality active transport experience'. In turn, 'maximise wayfinding' is one of ten purpose related functions (next level down) which are required in the system to maximise comfort. Further 'maximise wayfinding' is achieved through six object related processes that are enabled by a variety of physical objects within the footpath. In the WDA system described here the object related processes and their associated physical objects (in brackets) to 'maximise wayfinding' include: 'provide stop/go information' (traffic signals, regulatory signage); 'landmarks' (public art, trees, building setbacks, community archive and knowledge); 'footpath illumination' (pedestrian lighting); and 'provides wayfinding information' (road markings, cycle lane markings, regulatory signage, street name signage, information signage, tactile surface markers, building number signage) – all necessary processes and objects for maximising wayfinding.

For another example, when considering the value and priority measure of 'maximise actual safety' it is important in this systems approach to be able to offers means by which it may be achieved. It makes sense then that 'maximising actual safety' has connections with purpose related functions such as: provide protection for the travel-way; maximise lighting; minimise obstacles and debris; minimise changes in grade; maintain separation of pedestrians, cyclists and motor vehicles; maximise through zone clearances; minimise crime; provide warnings; design in consideration of the traffic context; maximise quality of the design; and corridor maintenance. These are all sound and adequate indicators of the level of actual safety, in turn supported by object related processes and the objects themselves.

Purpose-related functions

The purpose related functions sit at the middle level of the abstraction hierarchy. This level may be considered to represent the functions that need to be achieved for the system to fulfil its purpose. It is the crucial link between the independent objects and their related processes at the bottom of the hierarchy with the more purpose orientated concepts above. As such the use of the 'means ends' relationships are of significant value here for identifying the interfaces within the system. In the design context, this level represents design and end-user requirements in that they describe what functions need to be supported through design.

For example if it is considered that the purpose related function (minimise obstacles and debris) is the question '*what*', and the values and priority measures (maximise perceived safety,

maximise actual safety, and maximise subjective experience) are the question ‘*why*’, then the object related processes provide ‘*how*’ – prevents roadway water entering footpath, provide bike storage, protects and contains vegetation, stores litter and debris, provide surface for objects, provide access, store information on maintenance procedures.

Object related processes (physical affordances)

The physical affordances of the objects within the system relate to the ability of them to enable or aid a function. The description of these object related processes are such that they are generic and not a reflection of the active transport infrastructure system purposes. When linking the objects to their affordances it is evident that the object related purposes are often afforded by multiple objects. For example ‘provide shelter’ is an affordance of ‘trees’, ‘awnings’, and ‘public transit stop’. While objects which offer the affordance of a ‘landmark’ may also include ‘trees’ the affordance is also offered by ‘public art’ and ‘building setbacks’ in this WDA.

Physical objects

At the base of the AH the physical objects that comprise the active transport infrastructure system are detailed. At this level the objects, where possible, have been represented within the footpath zone in which they occur, and in Figure 3 are summarised as such. This is useful when considering the urban form and socio-spatial aspect of the system and the relationships between physical objects and the interface to the built form and (transport task) roadway contexts. Within the summary WDA there is an addition grouping of objects, which are important components of the ATI system that are not physically located within it. For example road rules; planning regulations; budget and engineering standards are crucial objects within the system, yet physically exist elsewhere. Key to this systems understanding is the recognition that many physical objects fulfil multiple affordances and so contribute to various purpose-related functions. For example a ‘planter boxes’ not only relates to the affordance ‘protect and contain vegetation’, but may also act as ‘physical buffers or barriers’ and ‘psychological buffer between the travel way and pedestrians’.

Discussion

The aim of this article was to demonstrate how CWA may provide a design template that will contribute to the design of more appropriate; safer and user orientated active transport infrastructure. It details a unique approach whereby it is possible to better understand the contributions that active transport infrastructure may make in operationalising hierarchy of best practice sustainable transport in existing urban corridors.

The analysis presented demonstrates the possibilities for the design of ATI that is context sensitive, well-engineered and that also contributes to the subjective experience of pedestrians and cyclists, possibly allowing for greater participation. Through constructing a generic WDA for ATI, this paper has provided a novel design template that may be used to inform the establishment of ATI. Additionally it is also useful to evaluate the extent to which existing ATI within urban corridors achieves anticipated and essential functional requirements.

A key contribution of this method, is that because the overall ATI ‘system’ is considered, it is possible to introduce different design features and then evaluate them in the context of their interactions with other parts of the corridor and thus their impact on the overall system itself. For example, in future design efforts one could introduce new objects in the AH and examine the means-ends links with functions, values and priorities, and the systems functional purpose. The analysis presented also reveals the significant influence of the many objects that are not physically contained within the actual footpath environment, such as planning regulation,

maintenance and design standards, and significantly for urban form and design the community archive and knowledge.

This study has allowed a clearer understanding of the contributions that physical objects, both within and beyond the urban corridor, make to the establishment of a leading practice ATI. Further it highlights the interdependency of many issues that have historically been managed in isolation and within discipline areas. For example, the engineering aspects of ATI are largely not expected to contribute to subjective user experience, and the urban design guidance on active transport and public urban environments has often relied on outlining principles without practical direction. This whole of system approach to ATI will enable consideration of this interdependency in future design efforts.

This paper identifies the usefulness of a systems approach in accessing disparate concepts. This system allows for an understanding of the interdependencies of intertwined functional purposes. It allows for multiple disciplines and indeed stakeholders to recognise their place within the system, and the impacts and influences of design decision-making. It makes sense that a systems approach allows for greater insights into the development of urban form. While this method has been applied to the socio-technical system of ATI, it is envisaged as a useful tool for a range of urban environments. Urban planning needs new ways to interpret built environments and urban form as not only technical systems, but often poorly understood (and designed) socio-spatial systems. Further research in which CWA is applied in urban design applications is therefore recommended.

Future Research

The application of the additional phases of CWA will assist in understanding how to best accommodate a variety of uses and users in ATI. Phases 2, 3, 4, and 5 of the framework consider important aspects of performance such as decision making, strategies, and allocation of functions and are important in determining how specific active transport infrastructure designs might shape pedestrian, cyclist, and motor vehicle behaviour. These stages will detail the types of activity permitted in different ATI designs and local considerations and contexts that impact on placement of physical objects and overall active transport infrastructure capacity. Further, allocation of functions across different physical objects will also be examined (for example, whether warnings should be provided to users via road and footpath markings or by signage).

As a preliminary study, this research will now be further extended in an application to an actual circumstance of ATI and assess the extent to which the current design fits the characteristics identified in the WDA model.

The Evolution of Urban Form

Analysing urban forms almost always involves a time dimension since human societies are not static. There were dramatic changes in town plans in the 12th and 13th centuries in European cities. Architects rediscovered geometrical techniques that had been lost since Roman times and applied them to both buildings and town plans. At the same time, and on a different scale, more stable building materials came into use (timber-framing and brick) which enabled buildings to survive for much longer time periods so that it was economically sensible to adapt them rather than rebuild. With the industrial revolution of the 18th and 19th centuries European cities grew rapidly and new house forms were developed to provide cheap housing for industrial workers. City centres were re-planned, adapted and rebuilt to provide greater functional utility. At the same time a multiplicity of new building types were developed to cater for new functions: from banks to prisons and shopping arcades to city halls. From the 17th to the 19th centuries European economies were extending their reach to new colonial territories and 'exporting' urban layouts to provide the necessary central-place and military functions, and the entrepôt economic functions, necessary in these colonial territories. Most of these new urban places were based on grid street patterns and common plot sizes and growth was demarcated by grid extensions, not always in congruence with their predecessors, based on underlying land-ownership patterns. The end of the 19th century saw a new morphological period develop in many parts of the world with low-density housing layouts characterising much of the Anglophone world and much higher density apartment blocks in other parts of the world. In city centres technological innovations led to taller office towers and the pace of morphological change at all scales became more rapid. In many city centres the life of buildings from new-built to demolition and redevelopment could be as short as 25 years, whilst concentration of capital resources has meant that huge developments can wipe out a thousand years of an intricate town plan and replace it with layouts lacking any historicity. Urban morphologists are still struggling to get to grips with the scale of some of these modern changes and integrate them into their models of townscape change.

Terry R Slater

Polish city from Conzenian perspective – fringe belt phenomenon in Toruń

Magdalena Deptuła

Department of Political Geography and Regional Studies, University of Łódź, ul. Kopcińskiego 31, 90-142 Łódź, Poland. E-mail: magbar81@wp.pl

Abstract. *The fringe belt idea is one of the most important concepts of urban morphology originating from Conzenian tradition. Being developed through over half a century it significantly evolved becoming not only an integral part of detailed town plan analysis but also a tool for synthetic comparisons of towns and cities of different regions and cultural contexts. In current literature on the subject a great attention is paid, among the others, on the influence of various processes, especially those resulting from different political and economic systems and ideologies, on patterns of fringe belt development. An often raised question is also the role of fortification systems in the process of fringe belt formation. The analysis of fringe belt phenomenon in the city of Toruń makes it possible to take an attitude towards above-mentioned issues in relation to Polish conditions. As an important political and administrative urban centre of medieval genesis Toruń experienced turbulent history, which was not indifferent to its urban structure. This paper seeks to outline how the following morphological periods, especially partitions of Poland, when Toruń was transformed into an important Prussian stronghold with double fortification zone, but also socialism period with associating it industrialization and controlled urbanization, influenced the specificity of fringe belt in Toruń.*

Key Words: fringe belt, fixation lines, historical development, Toruń, Poland

The fringe belt concept is the subject of numerous studies on urban form around the world. Examinations of fringe belts undertaken in many foreign research centers contribute to the dissemination of the idea and confirm its validity in relation to cities developing in different social and political conditions and different urban culture, irrespective of their size, genesis and function. At the same time they present how different developmental conditions influence the diversity of fringe belts in terms of their number, scale, structure and distribution in urban space. In Poland however, despite of a large interest of *Conzen's school of thought*, fringe belt concept has not, by now, been undertaken in native morphological studies. The only attempt of fringe belt analysis was the one of Terry Slater who in 1989 presented the town plan analysis of Lublin and characterized its inner and outer fringe belt for the year of 1762. Present study is therefore the second attempt to present the fringe belt phenomenon in Polish conditions, however the attention is drawn on its specificity resulting mainly from historically unstable political situation of Poland as a consequence of wars, Poland partitions and domination of communism system in post-war period. This conditions had direct influence on Polish cities which were mostly developed in isolation from the classical mechanisms of market economy, bid rent theory and decision processes that shaped the cities in the states of capitalist system. Therefore the main research purpose of the study is to present the specificity of fringe belt in the Polish city Toruń which has developed in a different cultural context and political, social and economic conditions, but most of all experienced the disturbed historical continuity of its spatial development.

Toruń

The detailed fringe belt examination requires a thorough analysis of the city, recognition of the stages of its historical development, its morphogenetic and functional structure, and understanding the processes underlying the changes of its spatial layout.

Toruń, which is now an important academic, cultural and economic center in Poland, with population over 204 thousands people and area of about 116 km², is a historical riverside port city situated on both sites of Vistula river, on contact point of two historical regions: Pomerania (right-bank part of the city) and Kujawy (left-bank part of the city). It is the one of the oldest cities of contemporary Poland and the first one founded by Teutonic Knights. Civic rights Toruń received in 1233. Being situated on the cross-point of main trade routes from Silesia, Wielkopolska, and Mazovia, in the place of passage through Vistula river, Toruń developed quickly as a main intermediary in trade with Eastern Europe, and became a well known Hanzeatic city. The choice of Toruń for the study of fringe belt was driven by a number of factors, both favorable and unfavorable for fringe belt formation, namely:

1. Toruń is a medieval city with distinct fixation lines (both anthropogenic and natural), which over the centuries experienced alternating periods of unusual dynamics of economic development as well as economic stagnation, what according to classic view of concept creates favorable conditions for fringe belts formation;
2. Since its beginnings Toruń played a significant defending role, which increased mainly during the time of Poland's partitions when Toruń became a part of Prussia. Prussian invader transformed the city into an important fortress on the border with Russia. The spatial reflection of this new function was the characteristic double fortification system: inner (surrounding the old core) and outer (located in a distance of 3-4 km from the old town) (Figure 1), but also a large scale of military development, which consequently restrained spatial development of the city;

Figure 1. Toruń fortress in 1889 with double (inner and outer) fortification system (Biskup, 2003).

3. Toruń during its history experienced multiple and severe destructions of its suburbs, starting from Swedish wars and construction of modern fortification system in 17th century, and ending with the construction of the Prussian fortress in 19th century which finally put the end to any traces of the former layout and buildings of the historic suburbs and obliterated the readability of its morphogenesis. Through over 800 years of its existence it also experienced the changes of its political membership – 223 years under Teutonic rule (1231-1454), 339 years within Polish state (1454-1793), 127 years under Prussian rule (1793-1920), and 88 years under Polish rules (1920-1939, 1945-2013). This lack of continuity of its historical development differentiates Toruń from most of cities subjected to fringe belt examination.

4. Moreover, unlike cities of western Europe, Toruń for a long period of its history has experienced controlled development, especially in the time of Prussian jurisdiction in 19th century, when Toruń was transformed into stronghold, but also in postwar period when Poland become a communist country subordinated to Soviet Russia authority and Toruń, as well as other Polish cities, experienced the functionalization of space as a result of socialism spatial planning, controlled urbanization and accelerated industrialization, which significantly increased the gap between Polish cities and Western European cities subjected to fringe belt examination.

It is also worthy to emphasize some characteristic elements of Toruń's spatial layout, namely: 1) the clear isolation of medieval core from extramural, relatively young suburbs, mainly from 19th and 20th century and 2) chronologically disturbed sequence of subsequent residential accretions – in the immediate vicinity of the old core one can find the residential buildings of the youngest genesis, mainly from 20th century, whereas further away occur the oldest 19th century residential buildings. The lack of hierarchical system of following residential zones and the lack of significant density of 19th century buildings around the medieval core are the result of, mentioned before, numerous and severe suburbs destructions. Moreover in 1813, in the place of former suburbs, the Prussian building restrictions were imposed, which until the end of 19th century prevented the spatial development of the city, at the same time favored the expansion of military land use types.

Similarly the essential communication network system of the city began to form relatively late – in second half of the 19th century. The contemporary road network has developed on the trace of the historical system of medieval exit roads as well as Prussian fortress roads – access roads and detours – which with time became a public roads joining suburbs. During the interwar period the steps in the construction of new roads were continued by Polish planners, and their main aim was to connect spatially isolated suburbs. Those actions resulted in formation of a road system which for subsequent years determined the trends in development of the suburbs, residential areas, squares, etc.

The construction of railway connections brought the qualitative change to the communication network system. The first rail connection (between Berlin and Warsaw) Toruń received in 1862. Until the beginning of the 20th century the city was already connected with Grudziądz, Malbork nad Lubicz. The construction of railway system has played a significant role in shaping the spatial and functional structure of the city. The railway station was located on the left-bank site of the city, what stimulated the further formation of the junction in this area, intensified the construction works and transformed the character of this part of the city from rural into suburb of workers and offices. On the other hand the course of the traction in the eastern part of the right-bank site of the city formed a barrier which spatially isolated the urbanized area from adjoining rural lands and, in the postwar period, determined the construction of a huge industry sector.

Having in mind a historic-geographical development of Toruń so distinctive from most of the cities subjected to fringe belts research studies, Toruń seems to be an appropriate case study for analysis of this type.

Sources

The examination of fringe belt in Toruń was based on town plans analysis and included reconstruction of historical development of the city based on comparison and analysis of sequence of historical plans supplemented by information from archive sources and research literature. The oldest preserved cartographic sources for Toruń originate from 1620s – the time of first Swedish war, however they only present a project of fortification system and do not give any information about the spatial layout of an old town or its suburbs. The value for fringe belt studies in Toruń have only plans starting from the end of the 18th and beginning of the 19th century, especially Douglas plan from 1793, Staudie and Gruetzmacher plan from 1816, and latter plans from 1873, 1903, 1907, 1921, 1939, up to postwar plans from 1973, 1983, 1999 and 2012. Most of the 19th century plans and interwar plans are small and medium scale maps, which provide the information about land utilization, sometimes block patterns, but almost no information about the plot patterns. Most of the postwar plans present the land utilization, block-plans and plot patterns. Having in mind this constrains the fringe belt examination in Toruń was carried out on block-pattern.

An useful supplement for the research were numerous studies, which reconstruct and describe the spatial development of the city in different historical periods, namely Tandecki (1995), Mikulski (1998, 1999), Biskup (1999, 2003, 2006), Gregorkiewicz (1967, 1974), Rymaszewski (1970), Tłoczek (1971), Kwiatkowska (1973), Niedzielska (1997).

Morphological periods

The historical evolution of the spatial structure of the city and the specificity of the morphological elements made it possible to distinguish five morphological periods fundamental for development of fringe belt components in Toruń, namely: 1) Middle Ages, 2) the modern times with an emphasis on period of Poland's partitions, 3) interwar period, 4) socialism period, and 5) contemporary period, started with political transformation of 1989.

The first period, referred to as initial, presents the stages of development of the Old Town and suburban areas of Toruń. During this time in the intramural and extramural part of the city the first extensive land uses occurred, namely monasteries, cemeteries, tanneries, mills and brickyards. Their peripheral location resulted mainly from limited area of the old town, but also from sanitary reasons, such as nuisance of production profile.

The second period covers the time of 'Prussian Toruń' and is considered twofold – in the context of the transformation of the city caused by the construction of the Prussian fortress (the role of double fortification system and Prussian building restrictions as a major fixation lines in fringe belts formation), and in the context of the spatial expansion of the city in the second half of the 19th century as a consequence of partial liquidation of outdated medieval and modern fortifications, gradual development of the inner fringe belt in the area of post-fortification zone, growth of the suburbs and creation of areas of tenement houses.

The interwar period was associated with further liquidation of the inner fortification system in Toruń, in place of which the new fringe belt land used occurred. At the same time further expansion of suburbs took place, where, apart from country houses and tenement houses, the single-family housing of villa character has developed. The process of suburbs connection begun (stimulated by Polish authorities), which was continued in the following years. The administrative area of the city was significantly extended (including the inclusion of left-bank suburbs into administrative boundaries of the city in 1936).

The establishment of the Polish People's Republic opens the fourth morphological period, when the spatial development of the city was subordinated to the unified spatial planning policy. It had its reflection in both: 1) transformation of the structure of existing fringe belts, as well as 2) creation of new fringe belts components dominated mainly by industrial function. In the sphere of housing construction, the development and metamorphosis of an earlier forms occurs, enriched with the elements of multi-storey socialist buildings. As a result of accelerated

industrialization, the rapid population growth, the development of the eastern suburbs and the expansion of the left bank site of the city took place. Simultaneously with the development of the technical and social infrastructure of Toruń, the process of filling with buildings of the empty spaces inside the city progressed, but also further connection of the suburbs and territorial development of Toruń occurred.

The last changes in the spatial structure of Toruń were initiated by political transformation of the 1989. The turn of the 20th and 21st century is characterized by the construction of large housing estates of single-family houses on the outskirts of the city, both right- and left-bank part of it, as well as further process of gaps filling spatial structure of Toruń. In the vicinity of the existing fringe belt, the new, specialized forms of development occurs.

Each of these morphological periods, which are in general relevant to most of Polish cities, has left in the spatial structure of Toruń a clear traces in the shape of extensive fringe belt land uses fulfilling the specialized functions. Obviously the scale and specificity of investments located in the actual fringe belt of the city were different in each morphological period. They were a consequence of functional structure of the city in different periods of urban development, the duration of each period, but also they reflected the actual socio-economic and political situation of the country. Not always therefore, the location of extensive development in fringe belt zone in subsequent morphological period, initiated the development of separate fringe belt. However it needs to be emphasized that in terms of the intensity of development and the specificity of fringe belt phenomenon formed in the spatial structure of Toruń two morphological periods are worthy special attention, namely 1) the period of partitions and 2) the period of Polish People's Republic, which at the same time emphasize the diversity of development of Polish cities with respect to their Western counterparts. Fringe belts formed in the time of partitions are characterized by relatively large spatial scope conditioned by the policy of the invader's authorities and the long time in which Poland was deprived of sovereignty. This period, in accordance with M.R.G. Conzen terminology, can be considered as formation phase. Fringe belts developed at that time formed the relatively sustainable basis attracting further specialized land uses of an equally extensive character, but younger genesis. Similarly, the analysis of the development of the spatial structure of Toruń in the communism period, allows to draw a conclusion, that through the establishment of functionalization of spatial development, it was a time conducive to growth of fringe belt components in the urban peripheries. Political changes and soviet ideology has found its reflection in spatial planning of Toruń, expressed in following plans of spatial development. Gradually a huge residential zones of blocks of flats, but also industrial and storage complexes, have dominated its landscape. As a result of individual, micro- and macro-scale decisions, accelerated industrialization and a tendency to zoning of the urban space, the new investments have been located on the outskirts of the city, in the former Prussian isolation wedges and fallow lands, and created new, or replaced an old fringe belt land uses. A great example is the peripheral localization of a huge plants of synthetic fibers, situated outside the city, however in close proximity to the outer bastion fortification system. It is also worthy to emphasize, that fringe belt components formed in communism time in Toruń, are creating a specific functional zones in the spatial structure of the city and are characterized by a number of developmental and structural differences comparing to classic model of fringe belt. However in the urban space they mark the lands of lower building density and indicate the former outskirts of the city.

Fringe belts in Toruń

Conducted research, based on town plan analysis of Toruń and reconstruction of its historical development, made it possible to identify two fringe belts in its spatial structure. The result of the research present three maps: first one, showing the general view of fringe belts in Toruń (Figure 2), second map presenting the genesis of preserved fringe belt components (Figure 3) and third one, indicating the actual land use types within fringe belts (Figure 4).

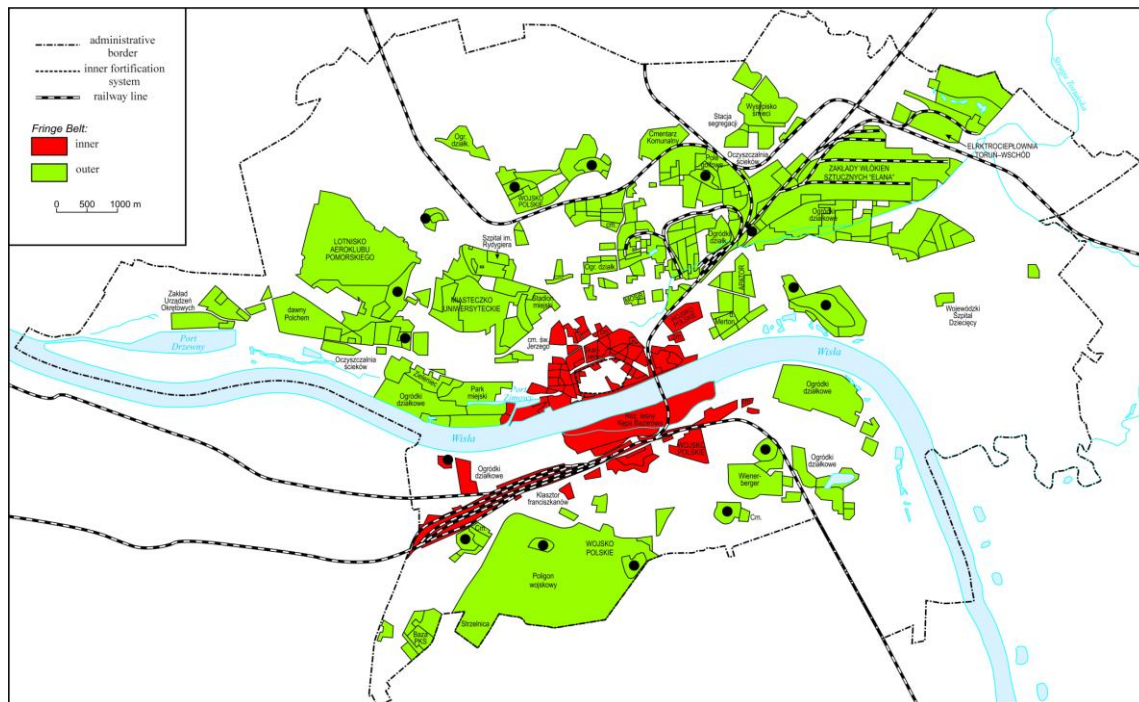

Figure 2. Fringe belts in Toruń, 2012.

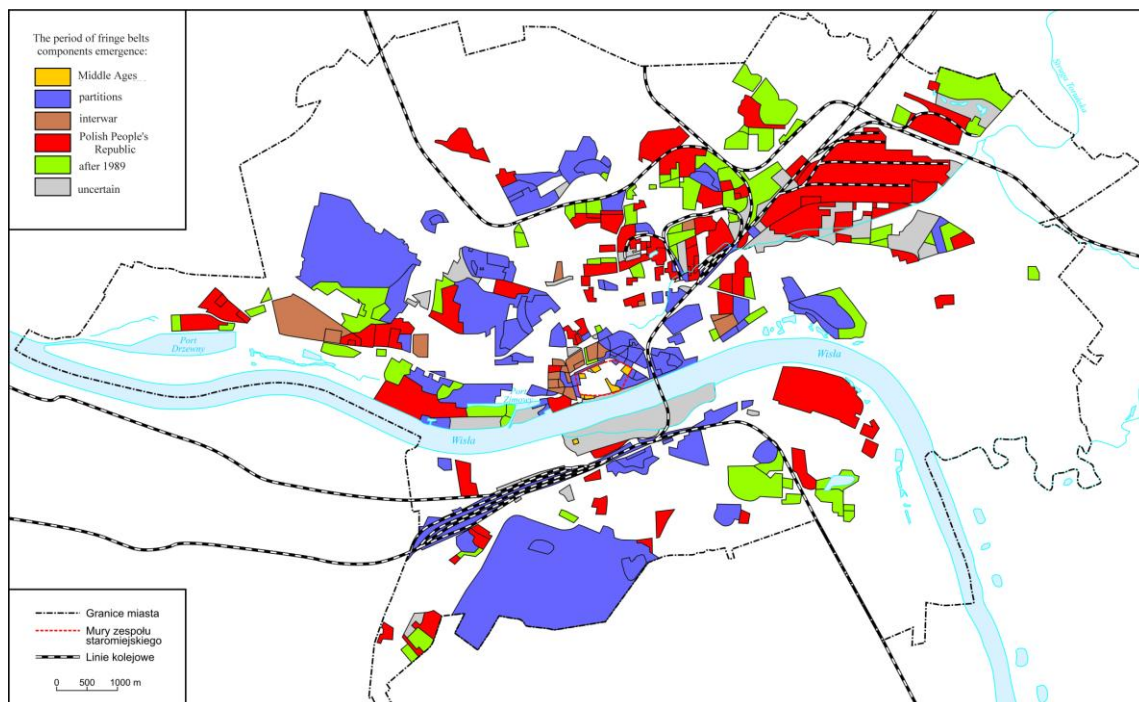

Figure 3. Genesis of preserved fringe belt components in Toruń.

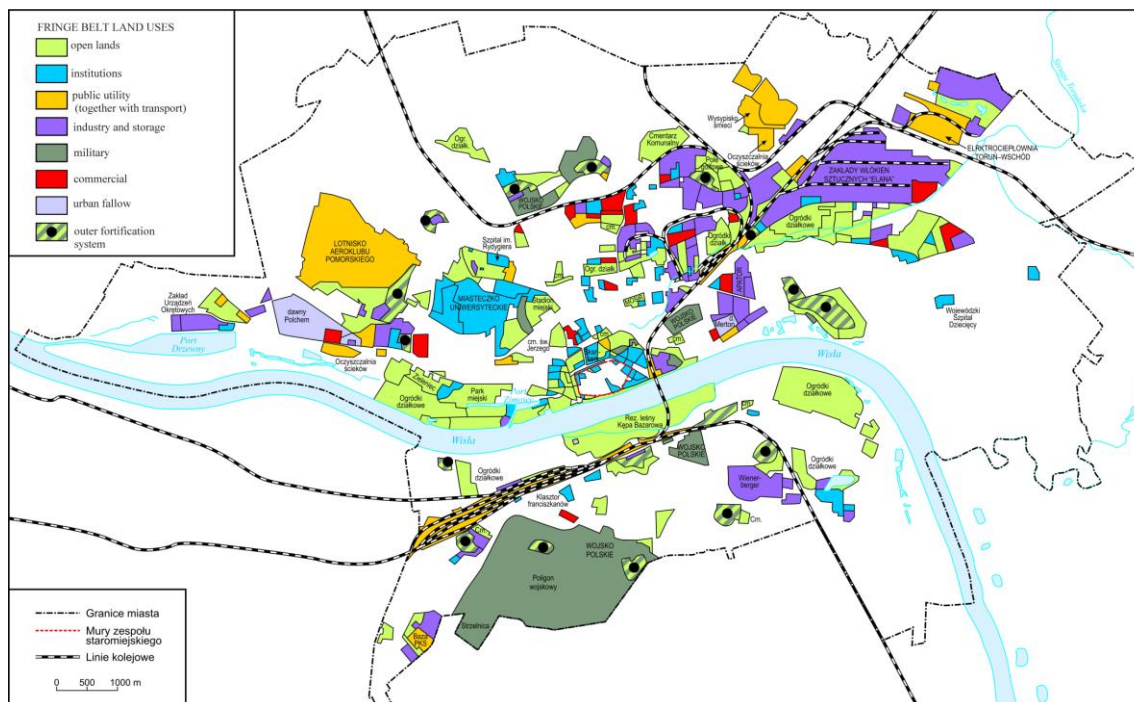

Figure 4. Fringe belts land uses in Toruń.

As a starting point for discussion on the number and size of fringe belt in Toruń the thesis of Michael Conzen was adopted where he states that the number and size of fringe belts appear to be related to the size and growth history of towns and cities (Conzen, 2009, p. 42). The detailed analysis of spatial development of Toruń seems to confirm this thesis only partially. Toruń, despite of its size has developed only two fringe belts, which is not too many comparing to case studies subjected to fringe belt analysis so far (e.g. Alnwick). At the same time the total size of fringe belts in Toruń is quite significant (together the inner and outer fringe belts cover about 35 km²). However this apparently disturbed proportions can be easily explained by recalling of historical events, that decided about the paths of spatial development of Toruń.

Inner fringe belt

The inner fringe belt of Toruń has started to form in medieval times together with peripheral location of specialized, extensive and heterogeneous land uses, like monasteries, cemeteries, hospitals, tanneries and others. However due to suburb's demolitions in different historical periods, all of the extramural fringe belt land uses were razed to the ground. The only medieval fringe belt components have survived in the intramural part of the city and are represented by the sites of the castle and its surrounding, and also former monasteries (Franciscans, Dominicans and Cistercians). An important role in inner fringe belt formation in Toruń has played the inner fortification system which has survived in the spatial structure of the city until the turn of the 19th and 20th century. The post-fortification zone was occupied by specialized fringe belt land uses, mainly of institutional and open character, which together with the intramural fringe belt components formed an inner fringe belt. Besides the role of the fortification system in the formation of inner fringe belt, also the influence of the decision making processes should be mentioned, among which the essential influence had the introduction of the Prussian building restrictions in the foreground of the fortress. As a result of that, the extramural part of the city was colonized by the military land uses, in shape of military barracks, military exercises fields and associated infrastructure. These land uses only partially have survived in the city landscape, however it influenced the extensive character of the contemporary inner fringe belt.

Moreover the inner fringe belt formation, was also influenced by the 19th century planning innovation together with the construction of so called 'ring' with dominant institutional development, and continued in the interwar period under a new name *pląty*.

The inner fringe belt of Toruń has many features reminding of the classic inner fringe belt in Conzenian meaning of the concept. It is characterized by a concentric, compact composition, large spatial coverage and diversified types of land use, mainly open lands, public utility and institutions. It forms a distinct pause in the spatial structure of the city, emphasizes the specificity of former fortification zone and separates residential zones of different genesis.

Outer fringe belt

However the specificity of Toruń emphasizes its outer fringe belt. It has started to form in the second half of 19th century along the fixation line in the shape of 19th century outer bastion fortification system, which is an example of military innovation designed in a large distance not only from the old town, but also from 19th century suburbs. Along this axis, starting from 19th century, and with intensification in after-war period, during the time of Polish People's Republic, the specialized, extensive fringe belt land uses accreted, contributing to spatial expansion of fringe belt and strengthening its distinctness towards surrounding lands. Therefore it needs to be emphasized that fringe belt components from socialism period did not form a separate fringe belt, but only enhanced the existing one. From most of the case studies subjected to research of this type Toruń outer fringe belt is distinguished by its large spatial scope of about 30 km², but also its general concentric composition with simultaneous occurrence of wedge futures, which are the consequence of Prussian authorities policy (e.g. Prussian isolation wedges) either the socialist power (e.g. eastern industrial district). What is characteristic, the process of outer fringe belt formation, which has started during times of Prussian annexation, still continues, what can explain its large spatial scope and diverse morphogenetic structure of its components. This fringe belt has not, by now, been surrounded by dense residential zone, which would cut it off from adjoining rural lands and forests, enabling fringe belt from further expansion. This is not however the result of a slow dynamics of spatial development of the city, but its mostly centripetal development, caused by the existence of large open lands reserve released from former military development. This specificity of spatial development of the city created the situation where outer fringe belt of Toruń does reflect the pause in the spatial development of the city, but in the same time it does not separate the residential zones of different genesis in the classical meaning of the fringe belt concept. It surrounds the extensive residential zone, that creates a morphogenetic mosaic, distorted in terms of chronology of following accretions.

Conclusions

The conducted research has proved the existence of fringe belts in Toruń despite of disturbed historical continuity of its spatial development. At the same time it indicated some similarities and differences between fringe belts formed in Toruń and fringe belts in classic model of phenomenon. Similarities concern the types of land uses and its specificity. Fringe belts in Toruń include mainly open lands, institutions, industry storage and public utility lands (together with transport), which are characterized by extensive kinds of development, relatively large plots and low permeability for vehicular traffic (Figure 5). Their common feature is a tendency to peripheral location on different historical stages of city's spatial development, therefore the fringe belts of Toruń reflect former and contemporary outskirts of the city. They are characterized by considerable degree of sustainability and reveal the strong spatial relation with fixation lines among which the long-term anthropogenic fixation lines, in a shape of fortification system, played the major role. Being an important barrier for free spatial expansion of the city

those two fortification systems have attracted extensive land uses originally mainly of military function which become a foundation for further fringe belt formation in following morphological periods.

Figure 5. Percentage of specialized land uses of fringe belts in Toruń.

However, despite of many similarities with classic model of concept fringe belt in Toruń differ from most of case studies subjected to researches of that type. Those differences refer mainly to the general arrangement of the phenomenon, the number of fringe belts and its spatial scope, and result mainly from different history, cultural traditions, political and socio-economic conditions. At the same time fringe belts of Toruń reflect its individual character, specificity functional structure of the city and influence of the various threshold conditions (fixation lines). Cities are in fact units of such a complexity that even strong similarities occurring between them, in terms of specificity and arrangement of fringe belt components reflecting successive morphological periods, do not obliterate their individual character.

Urban Evolution analysis as a means to confirm an outstanding example of a traditional human settlement in Rabat

Simone Marques de Sousa Safe, Staël de Alvarenga Pereira Costa

MACPS Escola de Arquitetura Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil. E-mail: simonesafe@globocom, staelalvarenga@gmail.com.

Abstract. *Rabat, capital of Morocco, received in 2012 a UNESCO World Heritage title for representing a modern urban planning model that incorporates the country's culture as it integrates its historical nucleus. Nonetheless, criterion (v) - to be an outstanding example of a traditional human settlement, land-use or sea-use which is representative of a culture (or cultures), or human interaction with the environment - has not been justified because the group presented seemed to be fragmented and showed lack of relationship between property and environment. This study considers to be an outstanding example of a traditional human settlement, the kasbah of Oudayas alone instead of the group presented in 2012. The aim of this study is to investigate the evolution of urban Rabat according to the morphological periods of developments, in order to reveal the historic areas in which the city has evolved over time, and ascertain whether or not it can confirm the kasbah as the most representative Islamic nucleus. The paper is useful for practitioners and academics in the fields of urban morphology and heritage, as much as for States Parties interested on applying to becoming part of the UNESCO's World Heritage list. The research provides some initial insight into how to investigate outstanding traditional human settlements and reveal their values. The approach adopted in this work demonstrates how the application and dissemination of a methodology may open new perspectives for studies on the subject.*

Key Words: English school of urban morphology; urban evolution; UNESCO world heritage; Rabat.

Introduction

The Kingdom of Morocco holds nine cultural properties protected as World Heritage by UNESCO. The newest is Rabat (capital), for its symbolism and diversity of traditions related to cultural property of populations.

Rabat is located in the northwest part of the country. It stands at the northeastern Atlantic Ocean coast at the Bouregreg River outfall, facing Salé, considered its "twin" city. The following maps present the geographical situation of Rabat.

Figure 1. Geographical situation of Rabat (source: Rabat's Culture Ministry -UNESCO's complete report: Rabat, Modern Capital and Historic City: a Shared Heritage. January, 2011 & Etude du schema d'organisation fonctionnelle et d'aménagement Casablanca-Rabat, 2005).

In order to be included in the World Heritage List, the sites must present outstanding universal value and fulfill at least one of the ten selection criteria established by UNESCO³⁷. Information hereby presented is part of the report produced by Kingdom of Morocco and delivered to UNESCO in 2011 to have its patrimony enrolled and evaluated. Rabat fulfilled criteria (ii) and (iv), according to ICOMOS³⁸ 1401 report: criterion (ii): to exhibit an important interchange of human values, over a span of time or within a cultural area of the world, on developments in architecture or technology, monumental arts, town-planning or landscape design; criterion (iv): to be an outstanding example of a type of building, architectural or technological ensemble or landscape which illustrates (a) significant stage(s) in human history. Those criteria were justified by the fact that Rabat has been considered an unique example of a modernist capital in the 20th century, a legacy of diverse and successive cultures. Such occupation shows evidence of continuity by its traces from various periods of time and also for the presence of monuments which reflects African, Mediterranean, Eastern and European cultures. As a result from European and Moroccan elements, the site acquired distinct character. Its capacity to demonstrate the lasting historical, cultural and social co-existence on the urban landscape shows the site *Genius Loci*.

Criterion (v) - be an outstanding example of a traditional human settlement, land-use or sea-use which is representative of a culture (or cultures), or human interaction with the environment especially when it has become vulnerable under the impact of irreversible - was not considered justified, as indicated by the 1401 ICOMOS evaluation. The presented ensemble - the Roman city of Sala, the royal necropolis of Chellah, the Hassan Mosque, the Kasbah of Oudayas, the medina of Rabat and the modern city - bears insufficient testimony to its relationship with a territory in which they operate, according to the evaluation. It was also considered fragmented, sometimes on a very small scale, which showed privileged relationship with a particular environment.

This paper proposes the kasbah of Oudayas as being the most traditional Islamic urban core in Rabat, Morocco. It investigates the urban morphological process in order to confirm this site as a World Heritage fifth criterion (v) candidate.

The Kasbah of Oudayas presents occupation by a majority of lower-middle class. Several interventions without authorization, lack of maintenance, examples of degradation and some abandoned buildings reflect on the built space in 2014. The kasbah's administration is made by the Bouregreg Agency since 2007, which is still elaborating solid instruments to manage this site. Being able to rely on an estimated budget for the conservation of this heritage, combined with strategies for heritage education with community involvement are possibilities that expand with the indication of such individual site as a world heritage.

Urban evolution study is the method proposed by the English School of Urban Morphology, which is used to investigate the urban process of Rabat. It seeks to demonstrate the relationship of the cultural property with its territory by detecting the morphological periods of urban development.

Morphological periods were identified based on historical references and on the Dr. Es-Semmar (director of patrimony of Bouregreg Agency) research about the urban evolution of Rabat-Salé over the past twenty-five centuries. Maps from the Rabat Master Plan were also used for better comprehension of the contemporary urban structure. Following the study of the urban evolution of Rabat.

³⁷ The list which holds the ten criterions can be found at UNESCO's website: <http://whc.unesco.org/en/criteria/> and they are explained at Operational Guidelines for the Implementation of the World Heritage Convention.

³⁸ International Council on Monuments and Sites.

The urban evolution of Rabat

The morphological study is based on historical and evolutionary periods, that should be differentiated according to Conzen (2004). Pereira Costa and Gimmler Netto (2013) define historical periods as those demarcated by facts, in which it is possible to settle dates like reigns, empires, and republican periods among others. In addition, evolutionary periods represent the synthesis between historical facts and materialized innovations into the urban landscape, defining formal characteristics. Such innovation could represent a start or an ending of an economical, social, political or/and cultural aspects, and are identified by specific formal characteristics.

In 2013, the same methodology was adopted in the city of Ouro Preto, Minas Gerais, by Staël de Alvarenga Pereira Costa et al, at landscape Laboratory EA/UFGM and it is a reference for this article. Based on this understanding, we have made the analysis to define the morphological periods in Rabat.

In Morocco, the historical periods considered relevant are: A - the period before the islamization (C5th b.C to C3rd); B - the Berbers influence (681 to 1554) and C - the Arabian influence (1554 to 2014).

Each era possesses political administration that forced changes within social life. In Rabat-Salé, during period A, three occupations were present: the Phoenicians, the Carthaginians and the Romans. Period B started with the Almoravids Empire (1100-1150), in sequence follows the Almohads (C11th to C12th) and the Merinids dynasty (C13th century to C16th). During period C, there were two major dynasties in power: the Saadian (1554 to 1650) and the Alaouite (1636 to 2014).

HISTORICAL AND EVOLUTIONARY PERIODS			MORPHOLOGICAL PERIODS
Before Islamization (5th century b.C – 3rd century)	Phoenicians, Carthaginians and Romans Periods	5th century b.C – 3rd century	Classic Period (C1st – C3rd)
Berbers – The Islamisation of the Kingdom of Morocco (681 - C 16th)	Almoravid Empire C10th to C12th	C12th 1100-1150	Ribat Almoravid period (C12 th: 1100-1150)
	Almohad Empire C12th to C13th	1150-1163 1° Calif	1° Ribat Al Fath Period (C12th: 1150-1163)
		1163-1253 2° e 3° Califs	2° Ribat Al Fath Period (C12th: 1163-1253)
	Merinid Dynasty C13th to C16th	1253-1609	Aribat Al Mobarak Period (C13 th to C17 th : 1253-1609)
The Arabians (from 1554 to 2014)	The Saadian Dynasty 1554 to 1650	1609-1666	The Moors period (from 1609 to 1666)
	The Alaouite dynasty 1636 to 2014	1666 - 1727 Moulay Rachid - Moulay Ismail	Golden Age Period (from 1666 to 1727)
		Sultan Sidi Mohammed ben Abdallah - 1757- Sultan Moulay Abderrahmane Ben Hicham 1790- Sultan Moulay Slimane 1912	Expansion and Consolidation Period (from 1757 to 1912)
		1912-1956 Rabat: capital	French Protectorate Period - Prost urban plan (from 1912 to 1956)
		1956-1972 Rei Hassan II	Period of Independence: Ecochard urban plan (from 1956 to 1972)
		1972 to 1990 Rei Hassan II	Rabat-Sale urban master plan of 1971-72
		1990 to 2014 Rei Mohammed VI	Rabat-Sale urban master plan of 1991

Figure 2. Board with morphological periods of Rabat (source: Conceived by the authors based on historical bibliography. April, 2014).

Twelve evolutionary periods were detected based on innovations and evolutions on the urban landscape of Rabat-Salé:

The Phoenicians, the Carthaginians and the Roman Empire - Sala Colonia (C5th b.C - C3rd)

The Almoravid Empire (C10th to C12th)

The Almohad Empire: 1st Caliph Abdelmoumen (1150 -1163)

The Almohad Empire: 2nd Caliph Youssef (1163) and 3rd Caliph Yacoub Al Mansur (1187)

The Merinids dynasty (1253-1609)

The Saadian dynasty - the Moors period (1609-1666)

The Alaouite dynasty - Golden Age (1666-1727)

The Alaouite dynasty - Expansion and Consolidation (1757-1912)

The French Protectorate - Rabat capital (1912-1956)

The Alaouite dynasty - Independency (1956-1972)

The Alaouite dynasty - Rabat-Sale Master Plan 1971-72 (1972-1990)

The Alaouite dynasty - Rabat-Sale Master Plan 1995 (1990-2014)

The morphological periods represent the synthesis between each historical and evolutionary period. Rabat's morphological periods synthesis are presented on the table below:

Morphological periods of Rabat

The morphological periods of Rabat are presented on three methodological basis, respectively related to the historical, evolutionary and morphological periods: historical event, innovation and urban form. These periods reveal the city of Rabat.

However, along to the sequence of morphological periods, a general introduction concerning the Kingdom of Morocco will be presented together with each historical period (before islamization, berbers and arabians).

Therefore, we begin with an introduction of the first historical period, followed by the first morphological period.

A – Before “islamization” (5th century b.C – 3rd century): Phoenicians, Carthaginians and Romans

Two Phoenician colonies of the nowadays Kingdom of Morocco - Lixus (Larache), in the north, and Mogador (Essaouira), in the south - made the connection route between North Africa and Spain while Cartago had not yet the domain in the western Mediterranean bank region. However, due to navigation difficulties of the time, other supporting commercial stations were founded between the both of them, such as Sala, and also Russandir, Tamuda, Tingis, Tchemmich, Banasa and Rusibis. Some of those cities appears in the figure below, spotlighting the existence the trading-post Sala.

Phoenician and Carthaginian archaeological traces of occupations cannot be found in Rabat anymore. According to Es-Semmar, their evidence are found in ancient texts which show trading commerce among the Phoenician and the amazigh native tribe, around the 5th century b.C. Likewise, later on they describe the exploitation by the Carthaginian of the same commercial spot, during the 3rd century b.C. The only archaeological traces that can be found in this site are then from the Roman Empire and they correspond to a military fortification that was as well used for commercial purposes during the first century b.C. Around two hundred years after this period, Sala Colonial appears as the first urban settlement, on the first century.

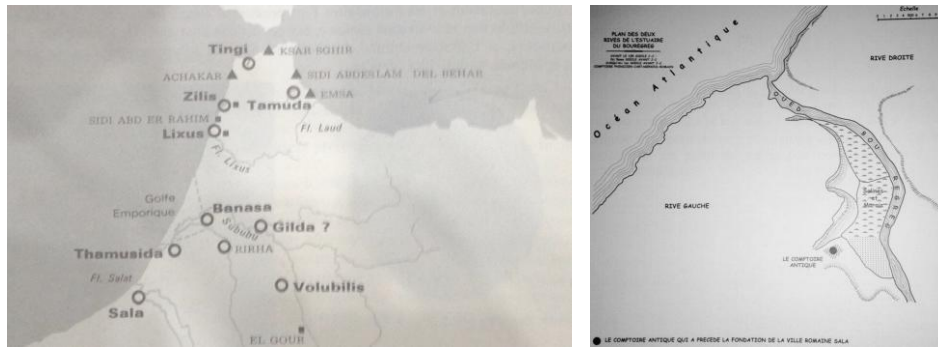

Figure 3. On the left, Kingdom of Mauritania; on the right, both Phoenician and Carthaginian trading-posts.(source: *Histoire du Maroc*).

1st morphological period: Classic Period (C1st – C3rd)

Historical event: Roman Empire (C 1st)

Innovation: trading settlement turned into a town - south capital of Mauritania Tingitane kingdom.

Urban form: urban settlement of Sala Colonia (in Rabat). The Roman city was conceived based on the existence of a protection wall, with a triumph arch, a forum, a main street, a basilica and public baths, as shown in the schematic sketch below.

Below town concept sketch and some pictures of the 2014 reminiscences.

All urban and architectural development throughout the following twenty centuries represents extension or continuity of this initial Roman settlement.

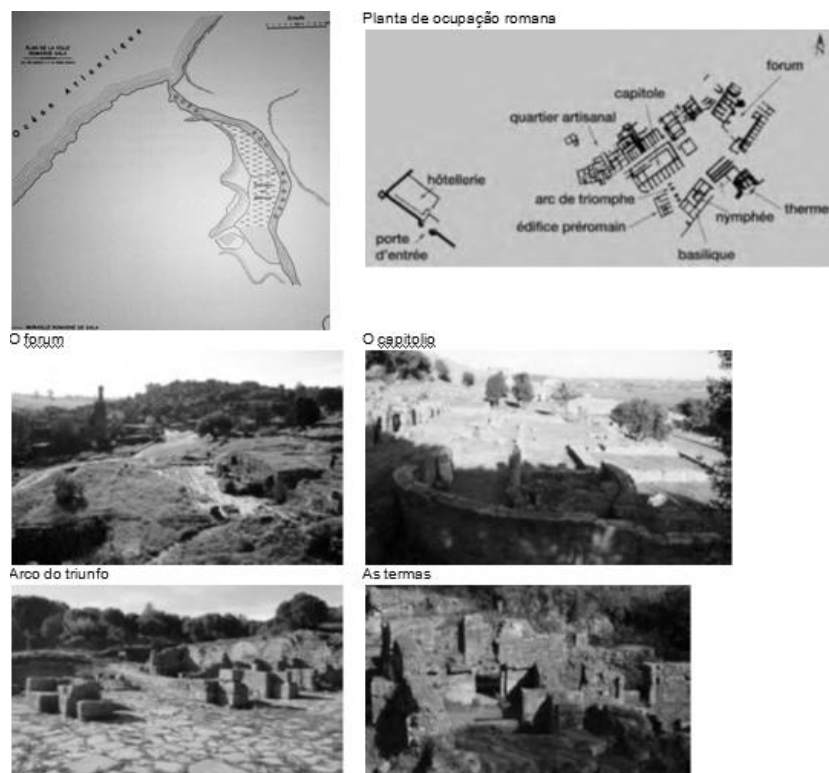

Figure 4. Sala Colonia (source: Dr. Es-Semmar, Heritage Director - Agency of Bouregreg. July, 2011 & Rabat's Culture Ministry - UNESCO's complete report: Rabat, Modern Capital and Historic City: a Shared Heritage. January, 2011).

B - Berbers – The Islamization of the Kingdom of Morocco (681 - C 16th)

The Mauretania Tingitana region was abandoned at the end of the 3rd century, but Sala (Chellah) remained under Roman domination during a less active period up to the end of the 4th century. It then entered a rather historical obscure period.

Between the C8th to C11th, the formation of muslin-Berbers enables the rise and the success of the almoravid's people, who came from the Sahara region, during a religious reform (Caillé, 2006). The Almoravid empire was founded by Youssof Ben Tachfin and lasted for about seventy five years. The conflicts between Arabs and Berbers are long and, historically, there are no literature consensus. In this article, we follow the references of Lugan (2011) and Brignon et al (1987), which say the occupation of the Maghreb is very atypical comparing to other Arabic conquers. The occupation of Egypt and Spain happened within three years. Iran's within four years and Syria's within six. Nonetheless, Maghreb's occupation took over a half century (Brignon et al, 1987). The conflict between Arabo-Muslim and Berbers was longer and during this period the region was Islamized, but not over-ruled by Arabic's. It is important to differentiate Islamization, religious concept, to arabization, ethnic-cultural concept, like Lugan (2011) says. According to the author, not every muslin is Arabic and vice-versa.

Regarding the urban content, this era holds the foundation of Fez – during the Idrissid Dynasty (789 - 808). It was the capital until the rise of the Almoravids' Empire (C 10th). The original Fez El-bali was conceived by two major fortifications separated by a valley. In the 11th century, the Almoravids connected both fortifications into a single one. Under the Almohad empire, the historical core of Fez grew up to the dimensions it presents in 2014.

During the Almoravid dynasty two other towns were founded: Meknes and Marrakesh. The last one became the capital of the empire until the rise of the merinide dynasty (13th century).

According to the report presented to UNESCO (Royame du Maroc, 2011), Arab historic sources refer to an abandoned ancient city, which however played a significant role in the Islamization of the region. A vast "ribat" is said to have existed in the 10th century, but up to now the most ancient Arabo-Muslim traces date back no earlier than the 13th century. What remained of the ancient city was abandoned for a new fortress, built by the Almoravids, in the early 12th century, to withstand growing pressure from the Almohads. The fortress was situated on the southern promontory of the estuary. The Almohad conquest took place in the mid-12th century, and it transformed the fort into a fortified palace, which today has become Kasbah of Oudayas.

2nd morphological period: Ribat Almoravid period (1100 to 1150)

Historical event: Almoravid Empire

Innovation: both Bouregreg river banks occupation - right bank, extension of Sala ancient town with Bani Ifren tribe instalation, for they were threatened by another tribe, the Bourhouatas from Tamesna. The following figure presents the location of the Bourghouatas reign and the little distance between its limits and Salé.

Figure 5. The Bourghouata's kingdom. (source: wikipedia).

On the left bank, expansion and foundation of a Ribat (military field): Ribat Tachfin, first Islamic occupation at the estuary promontory.

Urban form: city of Sala (in Salé) and military field Ribat Tachfin (in Rabat) presented below.

Figure 6. On the left, map with the Almoravid settlement; on the right, reminiscences of the Almoravid empire discovered in 2007.(source: Dr. Es-Semmar, Heritage Director - Agence du Bouregreg. July: 2011 & photography by Simone Safe in decembre, 2013).

3rd morphological period: 1^o Ribat Al Fath Period (1150 to 1163)

Historical event: Almohad Empire - 1st Caliph Abdelmoumen

Innovation: the rampart's pull down of the Bani Ifren's town on the right river bank and of the Almoravide's Tachfin Ribat pull down, on the left river bank.

Ribat Tachfin was replaced by the kasbah of Mehdiya, the urban core of the new planned city. In this empire, the Almohads had the intention of turning Rabat into the third empire capital, after Marrakesh and Seville.

Urban form: kasbah of Mehdiya. The following figure presents the geographic position of the kasbah of Mehdiya, featured in red.

Figure 7. First Almohad settlement - kasbah of Medhya (source: Agence Urbaine).

4th morphological period: 2nd Ribat Al Fath Period (1163 to 1253)

This period represents the first major expansion of the city.

Historical event: Almohad Empire - 2nd Caliph Youssef (1163) and 3rd Caliph Yacoub Al Mansur (1187).

Innovation: Completion of *Ribat Al Fath* town: ramparts and doors; Hassan mosque; the *kasbah of Mehdiya* river front extent and construction of the caliphate palace.

Urban form: *Ribat Al Fath*. Below, illustrative map with *Ribat Al Fath* settlement.

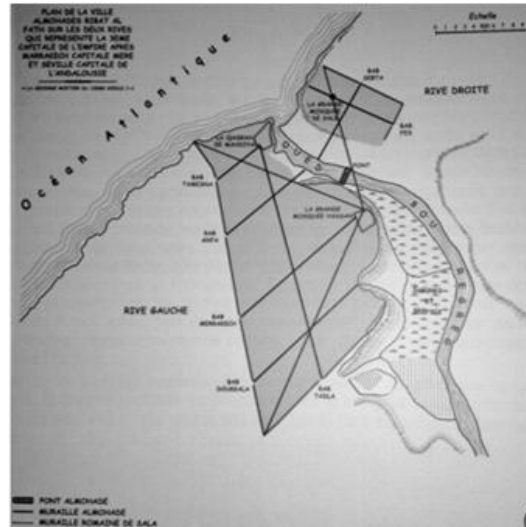

Figure 8. Ribat Al Fath town - Almohad Empire (source: Dr. Es-Semmar, Heritage Director - Agence du Bouregreg, July: 2011).

5th morphological period: Aribat Al Mobarak Period (C13th to C17th: 1253-1609)

- Historical event: Merinid Dynasty - Sultan Yacoub Youssouf e Sultan Abou Al Hassan.
- Innovation: construction of protective walls on the right bank, the region in which there was an attack by the Castilians in 1265.

The almohad urban area was mostly neglected and inaccessible (80% of 418 h were undeveloped).

The proposal of a new ribat, known as Aribat Al Mobarak, over the ancient ruins of the roman city Sala. Construction of ramparts and doors.

Apogee of Salé, on the right bank, as the main economic and urban center and port.

Urban form: fortified ribat and as the mausoleum of the dynasty. This ensemble is known as Chellah, in 1614.

Figure 9 presents illustrative a map. The Aribat Al Mobarak is colored in red and in brown, all ignored urban space. Figure ten presents pictures of Chellah.

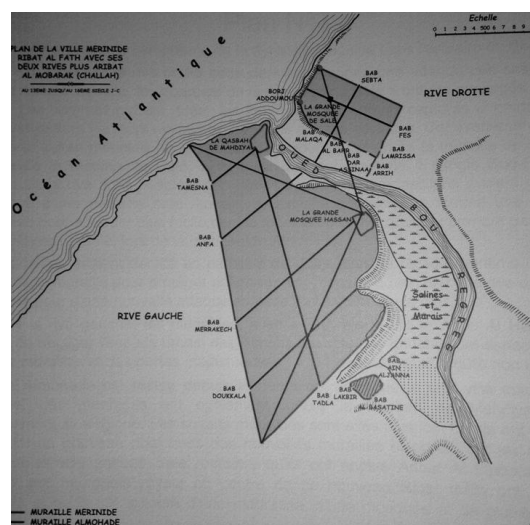

Figure 9. Merinid Dynasty - necropolis of Chellah. (source: Dr. Es-Semmar, Heritage Director - Agence du Bouregreg, July: 2011).

Figure 10. Aribat Al Mobarak (Royal necropolis reminiscences known as *Chellah*, 2014). (source: Agence Urbaine. Plan d'aménagement et sauvegarde de la medina de Rabat. Mission II - leve topographique, diagnostic et analyses thematiques et spaciales. June: 2012).

C - The Arabians (1554 to 2014)

The beginning of the sixteenth century shows crisis in Moroccan territory, due to the west Iberian conquest and the Turkish conquest in the east. The Ottomans want supremacy over the Spanish opponent and try to impose influence over Morocco. A new dynasty emerges, the Saadian, enabling a political, economic and intellectual renaissance. The Saadian were Arabs and, for the first time since the Idrissid dynasty, Morocco would not be ruled by the Berber people.

According to Lugan (2011), the word Morocco appears with Saadian, and it results from the contraction of Marrakech, the main capital of the dynasty era.

The Saadian century was a period of urban developments. Fès and Marrakesh intellectually dominate becoming cultural centers.

6th morphological period: The Moors period (1609 to 1666)

Historical event: The Saadian Dynasty. The expulsion from Spain of the Moors during the reign of Philip II (1609), by religious intolerance (Lugan, 2011). In the early 17th century, the Moorish immigrants set up a principality under the suzerainty of the Saadian sultans.

Innovation: The Moors expulsion led to a significant influx of Muslim and Jewish populations, who settled in the kasbah of Mehdiya and in the adjacent southern area. These populations of different origins built their own quarters: they founded their medina, called New Salé, protected by a wall in the south, dividing in two the large area enclosed by the earlier Almohad ramparts.

The not yet explored urban space, internal to the Almohad wall, was tapped with agricultural crops and gardens.

They also fortified the Kasbah, which became the center of their municipal power base. They engaged in port activities, making Rabat the premier port in Morocco.

Urban form: Medina of New Salé. Below map and photos with medina of Rabat and intrawalls green spaces.

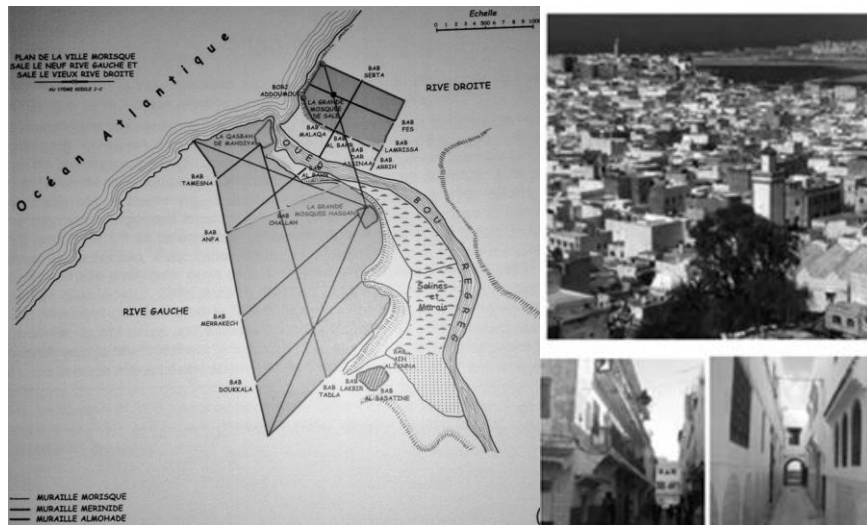

Figure 11. Saadien Urban occupation (source: Dr. Es-Semmar, Heritage Director - Agence du Bouregreg. July: 2011 & Rabat's Culture Ministry - UNESCO's complete report: Rabat, Modern Capital and Historic City: a Shared Heritage. January, 2011).

7th morphological period: Golden Age Period (from 1666 to 1727)

Historical event: The Alaouite dynasty - Sultan Moulay Rachid (1666 dC) e Sultão Moulay Ismail (1672 dC).

Innovation: Substantial construction works were carried out on a new fortress (operated as a prison during the French Protectorate and as a Military History Museum after 2010) and the Kasbah, including the prince's residence building, completed during the lengthy rule of Moulay Ismail. This palace became the second residence of the dynasty, after Meknès.

Urban form: illustrative map with emphasis in light blue representing extensions related to military and royal residence.

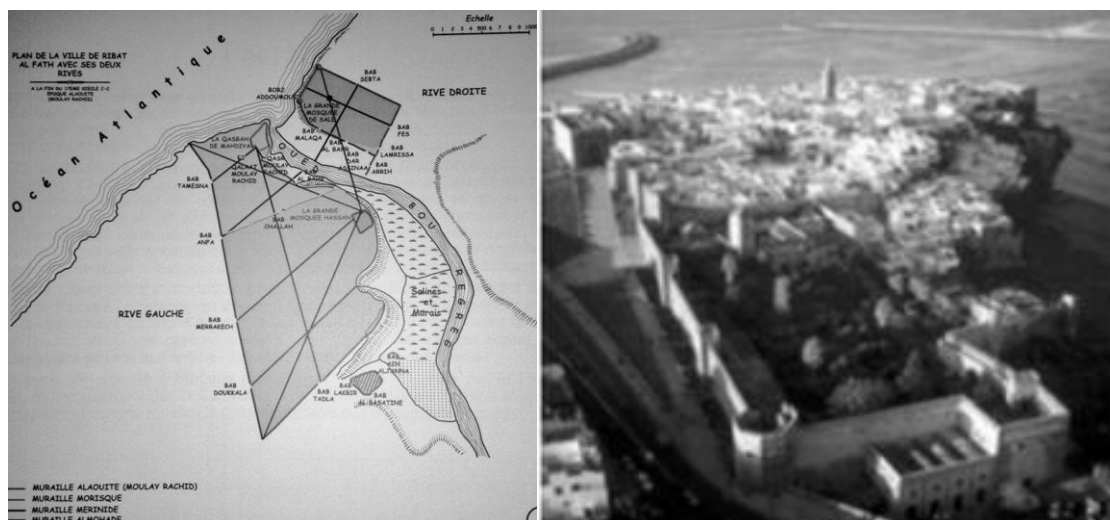

Figure 12. Moulay Rachid's expansion (light blue on the map on the left and picture with royal residence with garden on the right). (source: Agence Urbaine).

8th morphological period: Expansion and Consolidation Period (1757 to 1912)

This period represents the second great expansion in the urban context.

Historical event: Alaouite dynasty - Sultan Sidi Mohammed ben Abdallah; Sultan Moulay Abderrahmane Ben Hicham; Sultan Moulay Slimane.

Innovation: The defensive works continued on the site of the Kasbah with the construction of two *sqalas* (military surveillance towers). At that time, the *kasbah* was assigned to the warlike *Oudaia* tribe, which was the origin of the name.

The Alaouites had the intention of turning Rabat into the third empire capital, once again, after Marrakesh and Fès.

Construction of a new royal palace located intra-walls southeast (left map) with rampart for the Royal Alaouite new kasbah in the nineteenth century (right map).

Construction of three mosques in the axis connecting the palace to the medina's Bab Chellah door.

Construction of new rampart, south of the Almohad defense wall, creating protected new residential neighborhoods in the northwestern part of the urban space (left map).

In order to install gardens for the royal palace, Moulay Slimane also set limit known as "Agdal" in the southeast. (right map)

Construction of irrigation system for the new neighborhoods through the aqueduct of Ain Attiq.

Construction of secondary royal residence facing the Atlantic Ocean, at new urban space northwest (right map)

Foundation of the Jewish neighborhoods, called Mellahs, in Rabat and Salé.

Urban form: innovations are represented in the figure below, showing the changes in the urban form.

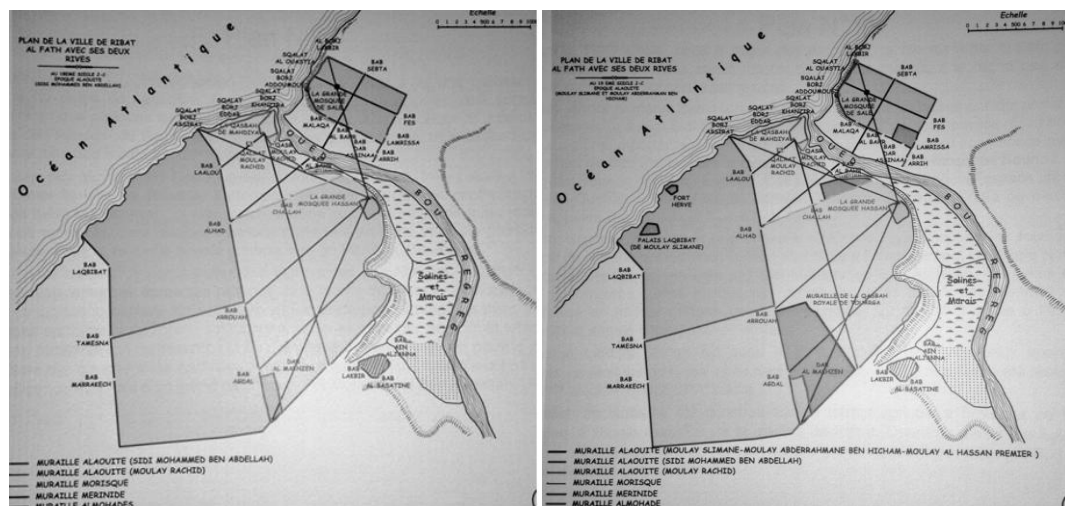

Figure 13. Alaouite dynasty urban occupation: on the left, C18th, on the right, C19th (source: Dr. Es-Semmar, Heritage Director - Agence du Bouregreg. July: 2011).

9th morphological period: the French Protectorate Period - Prost urban plan (from 1912 to 1956)

Historical event: the French Protectorate (from 1912 to 1956)

Innovation: Transformation of the city of *Ribat Al Fath* in the capital Rabat. Modernist urban plan, designed by Henri Prost, French urban planner. The project showed respect to the

traditional tissue integrity, while applying the most modern rules of urbanism. The multiple ramparts presented on the urban expansions remained.

The project represents the first urban master plan of the city, covering a total of 770 hectares. Salé was out of the master plan, because it was not considered part of the new capital.

The zoning was restricted to three sectors: residential and commercial conference center (35%), government (5.2%) and individual housing (44.2% - Medina of Rabat and 15.6% - Medina of Salé). The urban population in 1930, including Salé, was approximately seventy thousand residents. The following schematic plan shows Prost's planning.

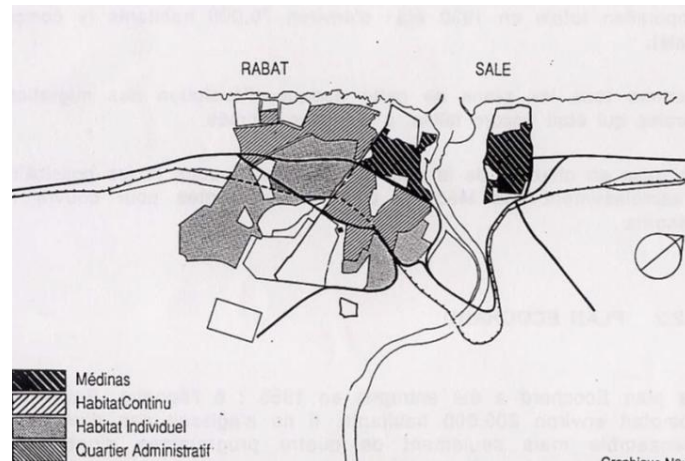

Figure 14. Modern Urban Planning by Henri Prost. (legend/up to down: medinas; multifamily houses; single house families; offices) (source: SDAU 1991).

Urban form: In the figure below, we can see the progress of urban structure during the period of the French Protectorate.

The period from 1941 to 1955 shows expansion of the residential neighborhoods at *Agdal* and *Souissi* (in lighter blue, at the bottom and left of the map)

Also, this period indicates the growth of two new neighborhoods in *Salé* (in lighter blue on the right)

It included the completion of a major public housing program, in the region of *Aviation* and western *Agdal* as well (lighter blue area at the bottom center).

Alongside these planned urban developments, others aggregates were informally and precariously installed in other parts of the capital.

Figure 15. Urban Structure evolution during the French Protectorate Period (source: Atelier parisien d'urbanisme. Plan d'Aménagement Unifié de la Ville de Rabat. Mission 2 - Diagnostic Analyses thématiques et spatiales. April: 2009).

10th morphological period: period of Independence: Ecochard urban plan (from 1956 to 1972)

Historical event: Alaouite dynasty - King Hassan II (1961-1999). End of the French Protectorate

Innovation: In 1955, a new urban planning was designed by the architect and urbanist M. Ecochard.

The project proposes four housing programs that are not intended to configure an unit.

Urban population: two hundred thousand residents.

New popular low-income housing forms to replace the existing slums. The designs were standardized around centralities that included essential equipment: mosque, *hammam*, school, market.

Construction of the express road reunites the city to the airport and other roads, allowing free access to leisure spots, such as the golf and hippodrome.

Urban form: Salé - bairros Hay Salam & Tabriquet neighborhoods, 190 he; Rabat - Yacoub El Mansur, 160 he, Youssoufia et takkadoun, 190 he and civil district at Agdal, in the west area, 106 he. Industrial districts follow the urban development of Salé and Yacoub El Mansur, respectively, 83 and 50 he (figure 15). See the master plan below with the Ecochard expansion proposal.

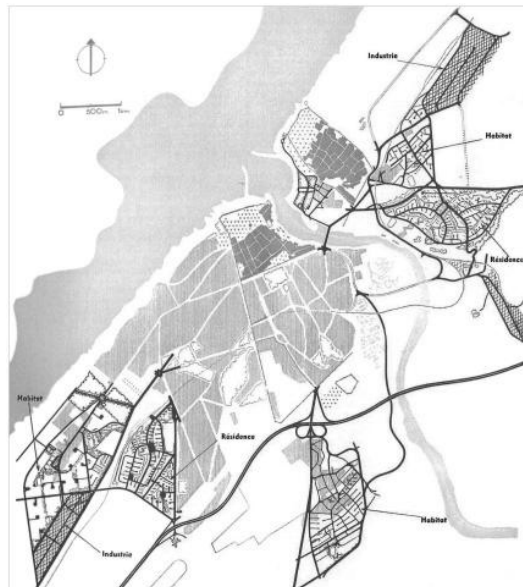

Figure 16. Ecochard Urban Planning. (source: Atelier parisien d'urbanisme).

11th morphological period: Rabat-Salé urban master plan of 1971-72

Historical event: Alaouite dynasty. King Hassan II (1961-1999). National attempted coup in 1971 and 1972, all the while Hassan II rule the reign with dictatorial powers. Unemployed and Students' dissatisfaction.

Innovation: 1971-72 Rabat-Salé's Master Plan along the objective of developing the roads and transport. The urban population in 1972 amounted up to 526 600 inhabitants, as reported by SDAU 1995.

From the Eighties, the Agdal neighborhood has become a business center, by the renewal of homes into buildings, in where some were occupied by offices and some by large upper middle class apartments, together with parking and services nearby.

Crucial program for clear and grassy spaces: a green corridor was proposed between the beach and the central area of Temara, a northern metropolitan's city. Also they've designed a green belt of 1200he between Temara and Rabat.

The figure below displays the map of the master plan 1971-72.

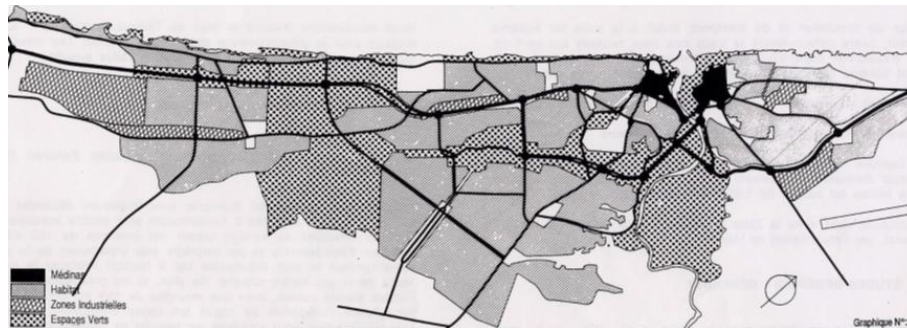

Figure 17. Urban Master Plan of Rabat-Salé 1971-72 (source: SDAU - Schema Directeur Rabat-Salé 1991).

Urban form: the Master plan was very different from that foreseen by an overestimation of population growth occupation.

More affordable institutional buildings were created at the Yacoub El Mansour and Hay Riad neighborhoods;

There were emergence of irregular housing as a consequence of underestimated calculation for Salé and Temara's regions;

Industrial areas estimated at around 1000he were overestimated. Precisely the 90he that was planned by Ecochard had been high-priced, the remainder being underutilized;

The following figure displays the urban structure' evolution at first master plan's period.

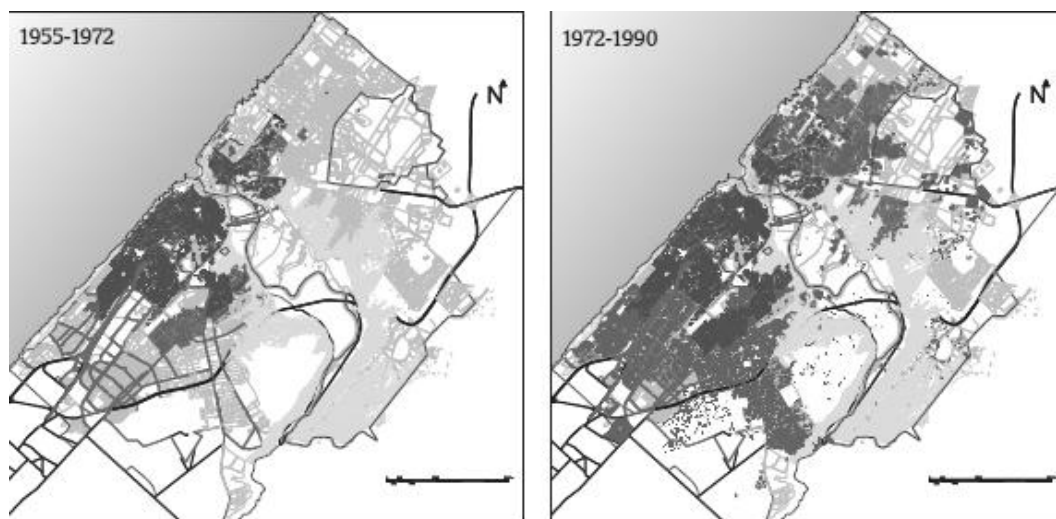

Figure 18. Urban Structure Evolution of Rabat after the first Urban Master Plan of Rabat-Salé 1971-72 (source: Atelier parisien d'urbanisme. Plan d'Aménagement Unifié de la Ville de Rabat. Mission 2 - Diagnostic Analyses thématiques et spatiales. April: 2009).

12th morphological period: Rabat-Salé urban master plan of 1991

Historical event: Alaouite dynasty - King Hassan II (1961-1999). King Mohammed VI (1999-2014).

Innovation: Rabat-Salé Master Plan 1991 is the current. Objectives: Real estate speculation control over land and the improvement of financing housing for disadvantaged populations; site, landscape and natural resources protection, particularly potable groundwater; improves running and transport.

From 1980 to the 2000s, the expansions happened along the coast and outlying areas.

Some neighborhoods have suffered greater density and growth than others. Urban Development: Riad Al Andalous neighborhood, restructuring the slum Al Kora and final stage construction of Hay Riad neighborhood.

Building of the Technopolis business area in Salé and Said Hajji and Sala Al Jadida operations.

Urban form: At that moment we find less urban expansion and major consolidation of the existing structure. The figure below represents the evolution between the two master plans, displaying by the lighter blue the urban form improvement in this period.

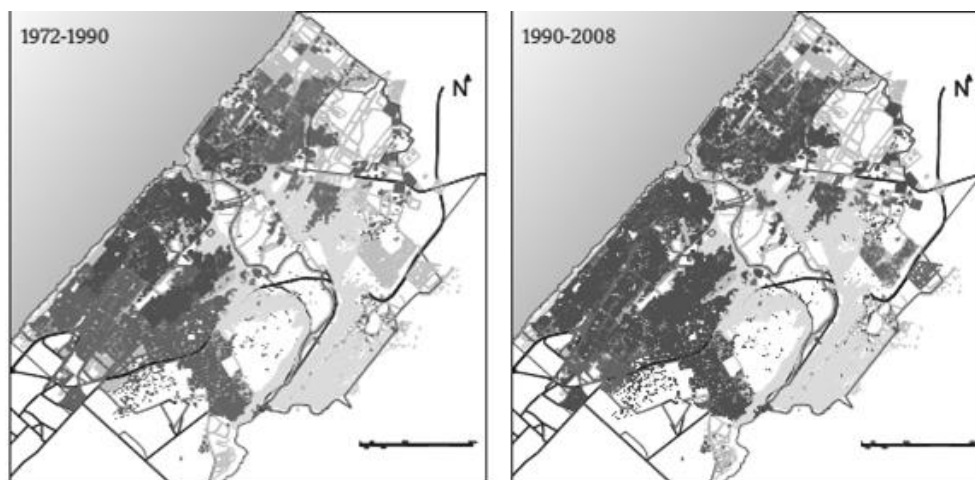

Figure 19. Urban Structure Evolution of Rabat after the second Urban Master Plan of Rabat-Salé, 1991 (source: Atelier parisien d'urbanisme).

Rabat's contemporary Urban Structure

Rabat morphological study case is an application of the method used by the English School of Urban Morphology intending to identify and analyse the historical urban landscape formation and evolution. By the example above, we recognized that the analysis focuses on the shape evolution, taking into account a range of historical and morphological periods.

The maps below show the Rabat urban structure in 2014, enclosing the transformations sequence highlighted by the morphological periods presented, through a concrete shape accumulation.

Figure 19 examples the urban structure evolutionary synthesis, showing that the period before 1913, time of French Protectorate installation, had presented in the urban structure only the traditional Islamic tissue, *kasbah* and *medina*.

Figure 20 shows the Typology Tissues in 2014, highlighting the attention for comprehending the position of the traditional urban tissue: this study's aim for proving the criterion (v).

The combination of the two maps shows that the considered traditional tissue is the oldest in terms of urban occupation, proving to be the original and so the most representative settlement of this place, and showing relation to the territory where it was installed and to the people who have ruled and printed their own culture, in every time.

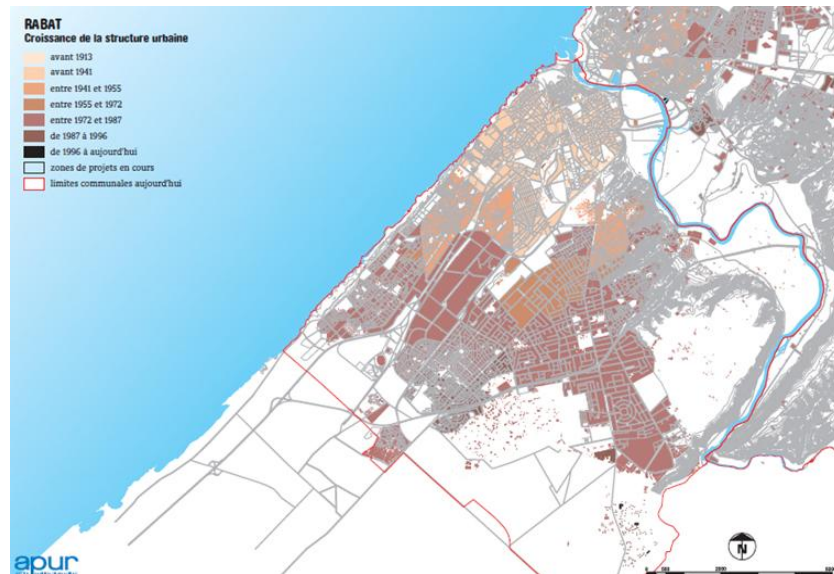

Figure 20. Rabat's Urban Structure Evolution (source: Atelier parisien d'urbanisme).

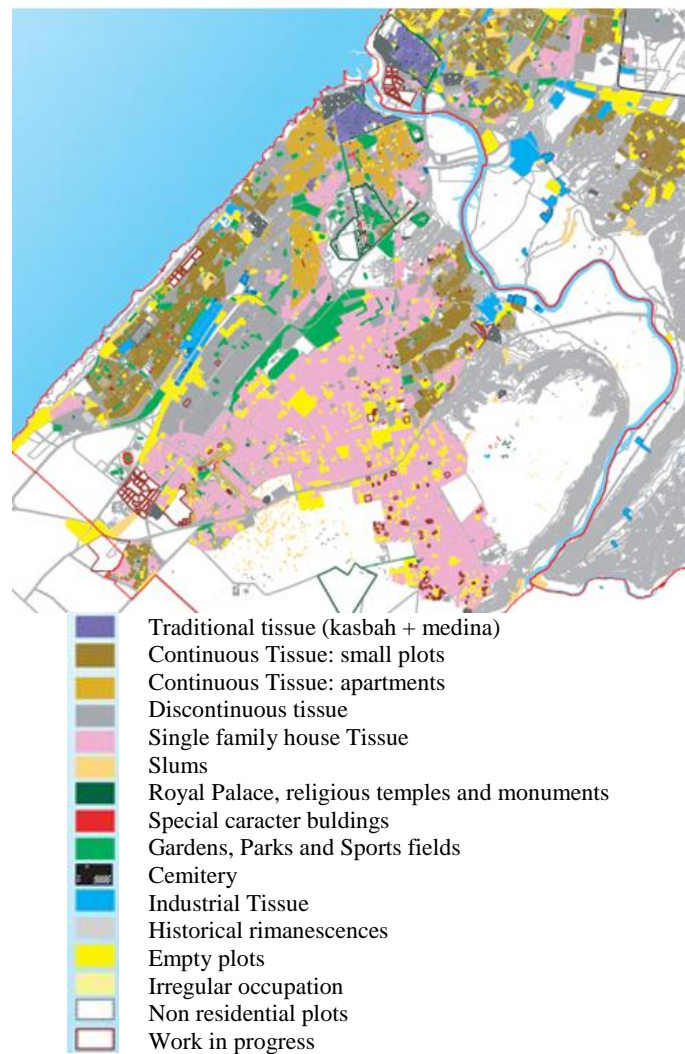

Figure 21. Typology Tissues in Rabat (source: Atelier parisien d'urbanisme).

Conclusion

The urban evolution study has proved to be a landscape interpreting method, able to understand the meanings of the shape as forces that have been influences, along the exposure of a landscape, a culture, a period values. The method as used in this article can opens the field for new applications. The urban morphology is being consolidated as a valuable tool for demonstrating originality, uniqueness and history of a place, UNESCO's valued characteristics part of more than one criterion.

The investigative method revealed the military fortification of Kasbah of Oudayas as the initial Islamic core in this region. This discovery turns the Kasbah as a potential candidate to meet the criterion (v), not justified in the dossier 2012.

The research of Rabat's fixation, expansion and consolidation phases have also demonstrated the site connection with the diversity of cultures - Berbers, Arabs and Westerners. The natural defence promontory position also points to the relationship between the original military fortification form and the operational environment, another criterion (v) desirable characteristic.

New questions have been added up to this study. What is the significance to Morocco of having an extra UNESCO cultural property and have accepted criterion (v) to the Kasbah of Udayas? It is worthwhile to ask the country's acceptance of this criterion again, after the application of this urban morphology method? What are the financial, heritage, education and management advantages that can be achieved from the UNESCO acceptance? Do the existence of historicity, valued by UNESCO in criteria (ii) and (iv) and highlighted by the morphogenesis analysis, create the possibility of men's awareness and education? Can this education be measured? Can it be awakened and encouraged?

Transformation of the fringe belt units within the perimeter of Avenida do Contorno/Belo Horizonte/MG

Karina Machado de Castro Simao, Stael de Alvarenga Pereira Costa

Architecture School, Urbanism Department, Federal University of Minas Gerais

E-mail: Brazil. E-mail: karinamdcs@yahoo.com.br, staelalvarenga@gmail.com.

Abstract. *This article maps out the transformations that have occurred in the inner fringe belt units located within Avenida do Contorno, Belo Horizonte / MG. Fringe belts, according to the concepts of urban morphology, are low density areas, often allocated for institutional use, and have a higher amount of free space in relation to nearby residential areas. They are classified, according to M.R.G. Conzen (1960), as inner, middle and outer, depending on their development over time and location. Conzen (2004) contended that the transformation of fringe belts included growth or reduction that may occur through alienation or transference. Such phenomena have constituted a widely researched area in European and American institutions that follow the English School of urban morphology. In this article, fringe belt units are identified and their transformation is analyzed individually. An evaluation is also made of the transformation of the three elements, recommended by Conzen, that make up the urban landscape (urban plan, built fabric and land use) of each fringe belt unit. The process of transformation in fringe belt units, revealed in the study, is reported in terms of increases or decreases and indicates that, for example, 30% showed an increase, whilst the remaining 70% manifested a reduction. The study therefore concludes that there has been a substantial and detrimental reduction in fringe belt units in Belo Horizonte.*

Key Words: Fringe belts, transformation, urban form, process, Belo Horizonte.

Introduction

The urban landscape is structured by morphological elements which include blocks, plots, roads, buildings, open spaces and fringe belts. These elements are conceptualized in urban morphology as spaces for institutional, low density use, and have a greater amount of open space in relation to nearby residential areas.

More specifically, fringe belts have physical characteristics such as, vegetated open spaces, occupation of buildings for institutional use or non-residential urban landmarks and sparse road networks with a low incidence of radial roads and low penetration of vehicles. Cemeteries, parks, villages, military installations, schools, hospitals, golf courses, football fields, monasteries all constitute examples of fringe belts. These morphological elements are classified, according to Conzen (1960), as inner, middle and outer in relation to their development over time and location.

Fringe belt study provides a base for a historical and geographical framework in urban morphology, since it permits the identification of the urban form's stages of development which are in turn intimately related to the physical configuration of the contemporary city.

This work aims to identify and analyze the units of the inner fringe belt located within the perimeter of Avenida do Contorno, Belo Horizonte / MG and the transformation of the belt's urban form. It furthermore attempts to: understand and recognize the characteristics of the urban landscape of the area; carry out a literature review examining the theoretical framework on urban morphology, focusing on the concept of fringe belts.

The methodological approach consists of applying the concepts of the English school of urban morphology, and the guidelines to fringe belt studies, developed by German geographer MRG Conzen (1960), which explains urban phenomena through the changes that occur in the division of land. This area of study, based on the English school, is familiar in European and

American countries. In Brazil, the few studies that address such phenomena include, Pereira Costa et al. (2009a, 2009b) and Meneguetti (2013). The method in question was applied in field work for the identification and characterization of fringe belts and has, as its aim, the analysis of the form and evolution of the inner area of Avenida do Contorno. This paper will thus present: (1) the method of identification (2) the fringe belt units mapped out on the perimeter of Avenida do Contorno (3) an analysis of the transformation of these units (4) the final considerations.

Identification of the fringe belt within the perimeter of *Avenida do Contorno* in Belo Horizonte/MG

For the identification of fringe belts in the city of Belo Horizonte, Pereira Costa et al (2009a, 2009b), considered a combination of morphological elements from low density and wide open spaces, to institutional installations (education, health, military, recreation, religious , among others) occupying reintegrated plots or blocks, as shown in Figure 1.

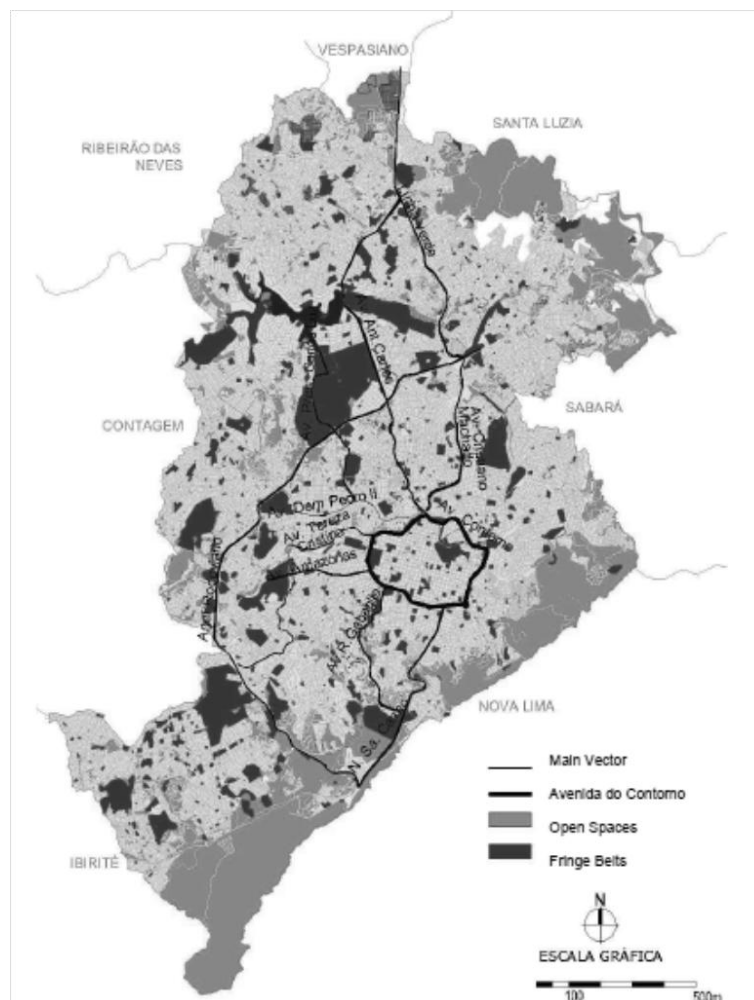

Figure 1. Open spaces and units of fringe belt identified in Belo Horizonte (source: Pereira Costa et al., 2009a; 2009b; 2010).

According to Pereira Costa et al (2009a, 2009b), the surface areas of the morphological elements that constitute the fringe belts equal 10% of the total area of the municipality. It can be observed in FIG.1 that these elements, identified in the city, have developed in a different

manner to those in traditional studies, since the geographical context of Belo Horizonte is different to those examined in traditional studies on fringe belts. These elements, identified in the city, are distributed in fragmented form, being composed of several units of fringe belt. This is corroborated by an analysis of the urban evolution of the city. By analysing the morphological periods it is possible to identify the location of fringe belt units and the existing occupancy rates of each period. From this identification, it is possible to assess if the units of fringe belt constitute an inner, intermediate or outer belt and identify the possible formation of rings, recurrent in traditional studies. The figure below shows the open spaces and units of fringe belt identified in Belo Horizonte.

The fringe belt units identified within the perimeter of Avenida do Contorno will be analyzed in the urban area of the city of Belo Horizonte, planned by Aaron Reis in 1887. These were chosen for their historical importance and central location. Furthermore, the area may have been subject to greater transformation since it is in this region that the process of urban occupation began.

The method used in this work consists of the superimposition of maps which facilitates an analysis of the permanence of these units in urban evolution and the urban, historical and economic context necessary to identify the units of fringe belt. The maps used in the study show the urban evolution of Belo Horizonte, the public institutions, public and private open spaces, the urban zoning and average gradient. Fieldwork was also conducted in order to confirm the previously identified elements.

The characteristics of fringe belt units

Fringe belt units, located within the perimeter of Avenida do Contorno, were identified according to their inherent characteristics and morphological elements, as defined by Conzen (2009). These criteria include: institutional land use; low density; larger amount of open spaces in relation to nearby residential areas; location on the boundary of urban occupation in each morphological period. Thus, forty-nine fringe belt units were identified within the perimeter of Avenida do Contorno, illustrated in Figure 2, according to the neighborhoods and Planning Units (PUs) in which they are located. The study area contains four Planning Units: Barro Preto, Centro, Francisco Sales and Savassi.

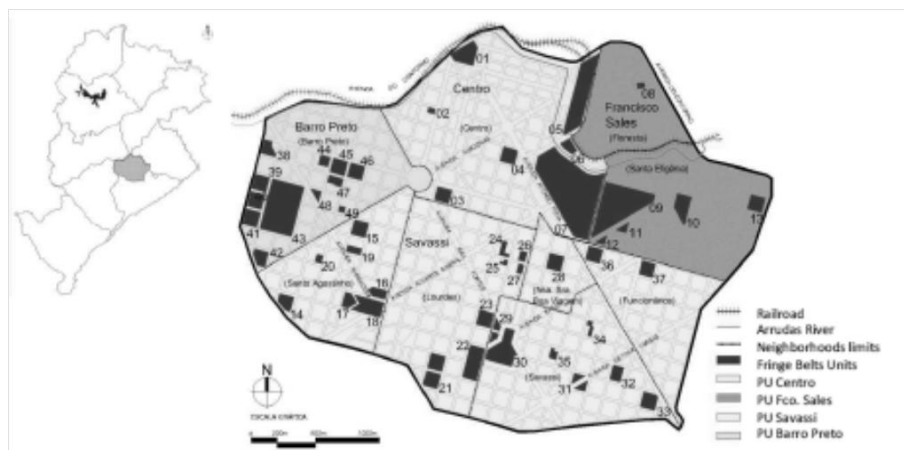

Figure 2. Fringe belt units identified in the inner area within the perimeter of Avenida do Contorno (source: Simão, 2012, p.62).

The first settlements and occupations occurred within the perimeter of Avenida do Contorno, Belo Horizonte. However, this area was not fully occupied as planned, due to the unexpected

growth of the city and the high value of land, which often characterizes the occupation of a Suburban Zone (FERREIRA, 1997). At the end of the period 1897-1935, the area occupied in the Urban Zone was relatively compact and polarized in the downtown area. Fringe belt units located in these unoccupied areas and on the edge of urban occupation constitute the IFB (Inner Fringe Belt), taking into consideration the morphological period and location.

Figure 3 illustrates this urban occupation, whose constructed buildings (occupied area) are marked by the shaded gray/black areas

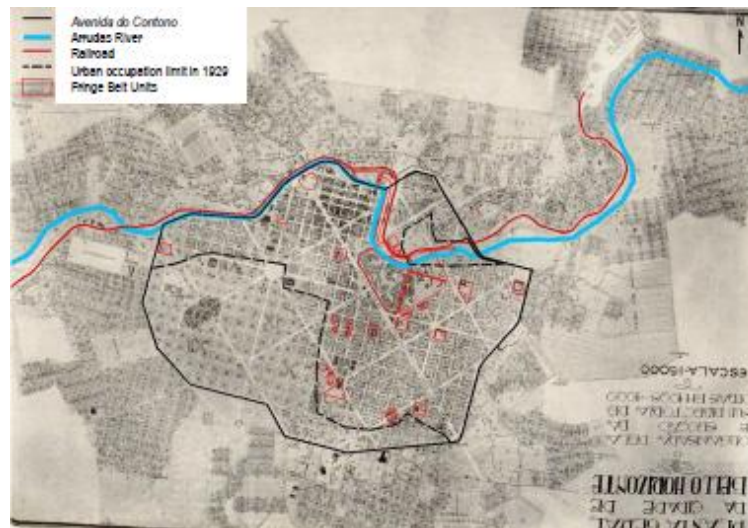

Figure 3. Registered plan of Belo Horizonte in 1929 and fringe belt units constructed in the period 1897-1935 (source: Simão, 2012, p.67).

The initial core of the central area in the urban zone is located near the River Arrudas - a topographically privileged area. The railroad was constructed to run through the original urban area. The river and the railroad became a double barrier that conditioned the subsequent occupation of the city (Lacerda, 1986). Therefore, the River Arrudas and the railway can be considered the first fringe belt line of demarcation in the study area.

The initial period of this urban occupation, from 1897 to 1935, can be considered a demarcation phase of the inner fringe belt, since it is related to the formation of the fringe belt which usually occurs around a line of fixation. Between 1935 and 2011, it is possible to observe the construction of new fringe belt units within the inner perimeter of Avenida do Contorno characterizing the transformation and consolidation phase of the inner fringe belt of Belo Horizonte.

The transformation of fringe belt units within the perimeter of *Avenida do Contorno*, Belo Horizonte / MG

Conzen (2004) believed that, among the three elements that compose the urban landscape, the urban plan (blocks, plots and road system) and the built fabric are more resistant to change, this characteristic being a reflection of the old pattern of land division and a factor in the preservation of a greater number and variety of traditional urban forms. Land use already responds more readily to functional changes, making historical study, through this element, more difficult. In order to assess the changes in the urban and built fabric and therefore, the smallest unit of urban form (the individual division and the buildings or the buildings and open spaces), the following maps of the area will be evaluated: planning and division Aarão Reis (1897), registered plan (1942) and aerial imagery (2011). In the analysis of land use, the history

of the buildings on the fringe belt will be studied and the zoning maps, in accordance with the laws of use and occupation of the city of Belo Horizonte established in 1976, 1985, 1996 and 2010, will be analyzed.

It is perhaps important to note here that according to Conzen's definitions (2004), the transformation of fringe belts include accretion (increase in area) or reduction, which can occur through alienation (loss of area for commercial or residential use) or translation (change in the type of land use from an old fringe belt to a more recent one in the same location). The transformation of the three elements that compose the urban landscape (urban plan, built fabric and land use) will be analyzed on each fringe belt unit and this process of transformation will be reported as an accretion or reduction (alienation or translation).

The fringe belt units identified and their transformation was analyzed individually by Simão (2012). According to the author, twenty three units of the fringe belt underwent transformation, comprising 46% of the total forty-nine (units). In this work, three out of the twenty and three fringe belt units which underwent changes, were selected for illustration. They are: the Municipal Park, Santa Casa de Misericórdia Hospital and the unit composed of the Luiz de Bessa State Public Library, Police Command of Minas Gerais and the Palace of Liberty (Palácio da Liberdade), as shown in the following figures.

Municipal Park

According to Maciel (1998), the park's location was chosen by Aarão Reis as the main area for public leisure and a reference point for his design of the city (Fig. 4). However, only a quarter of the planned (555.060m²) area was occupied as an public open space. In 1907, the southern area was chosen to house a municipal institution and in 1909, the northern region was split into nine blocks (Horta, 1988). The area of the park, therefore, was reduced from 555.060m² to 352 562 m².

In 1942, the built area on the block occupied by the Health Campus (South) was 11.200m² and the open area 91.920m², of which, 47% was vegetated (43.426m²). The occupation density was 10%. In the same period, the block marking the park's location was divided into three (Fig. 5). It is thus possible to observe a change in the urban plan and the free and permeable areas of the park were once again reduced (from 352 562 m² to 182.820m²).

A Map from 2011 (Fig. 6) shows the block formerly occupied by a stadium (east) divided into three. Therefore, the only block planned for the park was divided into fourteen as from 1909. The built area occupied by the Health Campus (South) block manifested an increase from 11.200m² to 42.511m²) while occupation density increased from 10% to 40%. Open space was reduced from 91.920m² to 60.609m², to such an extent that the vegetated area fell from 43.426m² to 10,326 m². Besides the transformation of the urban plan and built fabric, it is possible to witness changes in land use. This is due to the fact that, according to the Law of Use and Occupation 1976, 1985 and 1996, the blocks on which the park and the Health Campus are located, are classified, respectively, as SE-2 (Special Sector 2³⁹), SE-1 (Special Sector 1⁴⁰) and SE-2 (Special Sector 2), ZPAM (Environmental Protection Zone) and ZCBH (Central Area of Belo Horizonte⁴¹).

The block planned by Aarão Reis for the Municipal park was subject to a reduction through transfer as there was a change in the type of land use in the area after its inauguration (from

³⁹ SE-2 are spaces, facilities and installations subject to control and allocated for grand institutional use such as: parks, squares, hospitals, civic centers, universities, stadiums, terminals, garbage plants, landfills, cemeteries, leisure areas and schools in general (Belo Horizonte, 1976).

⁴⁰ SE-1 are the spaces, establishments and installations subject to preservation or specific control, such as: areas of landscape preservation, the protection of streams and woods, natural forests, forest and mineral reserves, historical monuments and areas of strategic value to public safety (Belo Horizonte, 1976).

⁴¹ Art. 11 - ZC's are the configured regions such as regional, municipal or metropolitan centers (Belo Horizonte, 1996).

public leisure to health facilities). Because of this change of use, there occurred a transformation in the urban plan through the division of the single block (planned for the park) into fourteen smaller blocks. The location of the block next to the River Arrudas valley can be considered as an important morphological element as it came to function as a demarcation line and barrier to the extension of the Municipal Park and contributed to the consequent fragmentation of the area. The new plan led to the transformation of the built fabric, by increasing the built area and decreasing areas of open space, especially the block occupied by the Health Campus / UFMG (Federal University of Minas Gerais).

The built area on the block occupied by the park presented no increase in the rate of occupation, probably due to its classification in Municipal Law No. 7166/96 as ZPAM (Environmental Protection Zone) and its preservation as a Landscaped area in 1975. However, there has been a 67% reduction in the in the park's permeable open area (from 555.060m² to 182.820m²) and 34% in the open area of the block on which the Health Campus / UFMG is located (from 91.920m² to 60.609m²), resulting in a large loss of permeability.

(impermeable).

Santa Casa de Misericórdia Hospital (10)

According to the Aarão Reis plan, the two blocks occupied in 1911 by the Santa Casa de Misericórdia Hospital were orthogonal, one of which became triangular on being divided in the construction of Avenida Francisco Sales, the latter following a diagonal trajectory. The first wing of the hospital was opened in 1903, occupying the non divided square format block (14.400m² area). The triangular-shaped block was divided into seven plots (Fig. 7). By the year 1931, the current block (2011) was divided by Rua Padre Marinho, according to the Aarao Reis urban plan.

Horta (1988) noted that Rua Padre Marinho was deactivated in 1937 and in 1940 the existing hospital building (2.785 m²) was constructed (Fig. 8). The area of the block was increased from 14.400m² to 20.690m² and the occupation density in 1942 was 13%, with 87% of the open area being impermeable. After the deactivation of the street and junction between the blocks, there occurred a transformation in the urban plan, however the triangular block remained intact.

In 2011, new buildings were attached to the hospital (Fig. 9), totaling a built area of 8.645m². The occupation density increased from 13% to 42%. The impermeable open area of

the block was reduced from 87% to 58%. The block was then respectively classified as SE-2 (Special Sector 2), SE-2 (Special Section 2), and ZCBH (Central Area of Belo Horizonte) in the Use and Occupation of Land Legislation of 1976 1985 and 1996.

The block occupied by Santa Casa de Misericórdia Hospital was increased because of the deactivation of Rua Padre Marinho and the union of the two blocks that compose the current block thus generating a transformation in the area's urban plan. Despite continued use as a hospital area, this fringe belt unit underwent many changes in the built fabric with the construction of new buildings and the reduction of the block's impermeable open area.

Figure 8. Santa Casa de Misericórdia Hospital BLOCK in 1911 (source: SIMÃO, 2012, p.101). Block Área: 14.400m²

Block Area: 20.690m², Built Área: 8.645m², Open Área: 12.045m² (impermeable),
Occupation Density: 42%**

In 2011, new buildings were attached to the hospital (Fig. 9), totaling a built area of 8.645m². The occupation density increased from 13% to 42%. The impermeable open area of the block was reduced from 87% to 58%. The block was then respectively classified as SE-2 (Special Sector 2), SE-2 (Special Section 2), and ZCBH (Central Area of Belo Horizonte) in the Use and Occupation of Land Legislation of 1976 1985 and 1996.

The block occupied by Santa Casa de Misericordia Hospital was increased because of the deactivation of Rua Padre Marinho and the union of the two blocks that compose the current block thus generating a transformation in the area's urban plan. Despite continued use as a hospital area, this fringe belt unit underwent many changes in the built fabric with the construction of new buildings and the reduction of the block's impermeable open area.

Luiz de Bessa State Pública Library, Minas Gerais Police Headquarters (29) Palace of Liberty (Palácio da Liberdade) (30)

According to the Aarão Reis plan, the Palace of Liberty should have occupied a block with an area of 7.150m², including the surrounding roads (Fig. 10). In 1925 (Fig. 11), the block on which the palace was built in 1897, quadrupled in area from 7.150m² to 27.700m², further growth being restricted by Rua Borba Gato which was deactivated as can be seen in the 1942 plan (Fig. 12). Here, the extension of the block occurred through the deactivation of a stretch of road. However, the palace's plot was reduced from 27.700m² to 24.200m², since the remaining plots were occupied by residences. In 1942, the built palace area was 940m², with an occupation density of 4% and an open area of 23.260m², 20% of which was permeable (4.980m²).

In 2011 (Fig.13), the built palace area increased from 940m² to 4.600m², owing to the construction of a new administrative building (1.300m²) and new Palace buildings (2.360m²). Thus, the occupation density changed from 4% to 20% and the total open area was reduced from 23.260m² to 19.600m² (permeable). Also observed in Fig. 52 is the construction of a new institutional building. In addition to this, as shown in FIG. 12, the block occupied in 2011 by the Luiz de Bessa State Public Library and the Police Command of Minas Gerais was divided by Rua Tomaz Gonzaga into two blocks with an area of 3.700m² (each) and the buildings had not yet been constructed. Figure. 13 shows that the street had already been deactivated and a single block with an area of 8.500m² occupied by the library (1.360m²) and the police command (1.000m²) with an occupation density of 50%.

The Blocks occupied by the Palace of Liberty and the Luiz de Bessa State Public Library were extended due to the deactivation of Rua Borba Gato and Tomaz Gonzaga and there thus

occurred a transformation in the area's urban plan. Despite continued use of this fringe belt unit, there was a change in occupation density owing to the construction of new buildings and a reduction in the open area of the block on which the Palace of Liberty stands.

An Individual analysis of the transformation of the twenty-three fringe belt units resulted in Table 1, which illustrates the change in occupation density, permeability of open space and classification of transformation according to Conzen (2004).

Figure 11. Palácio da Liberdade in 1897 (source: Simão, 2012, p.110). Block Área: 7.150m²

Figure 12. Palácio da Liberdade in 1925 (source: Simão, 2012, p.110). Block area: 27.700m²

Block/Plot Área: 24.200m², Built Área: 940m², Free Área: 23.260m²: 4.980m² (permeable)
and 18.280m² (impermeável), Occupation Density: 4%

Figure 14. Palácio da Liberdade in 2011 (source: Simão, 2012, p.110).
Block/Plot Área: 24.200m², Built Área: 4.600m², Free Área: 19.6000m² (permeable),
Occupation Density: 20%

An Individual analysis of the transformation of the twenty-three fringe belt units resulted in Table 1, which illustrates the change in occupation density, permeability of open space and classification of transformation according to Conzen (2004).

The transformation analysis of each fringe belt unit inserted within the perimeter of Avenida do Contorno (Table 1) indicates that, out of the forty-nine elements identified, fourteen of them (30%) were subject to alteration, four of them (30%) by extension and ten (70%) by reduction.

Source: Simão, 2012, p.102.

Six units of the fringe belt (60%) were reduced through transference and four (40%) by alienation. Therefore, most of the transformed fringe belt areas were reduced.

With regards to the change in the urban landscape component, twenty three fringe belt units, which account for 45% of all those identified, had their urban plan, built fabric or land use transformed. In the fringe belt units that underwent extension, there was a change of urban plan and the built fabric. For those which were reduced through transference, there were modifications in the three elements: change in land use; built fabric; alienation. In the case of the other fringe belt units (nine out of the twenty-three - 40% of the total) which did not undergo extension or reduction due to alienation or transference, the built fabric was transformed (an

increase in built area and reduction in open area), or be it, the block underwent a reduction in free space.

Of the twenty-three fringe belt units that had a morphological element of the urban landscape transformed, all of them had their built fabric transformed, nine with changes in land use and eight in the urban plan (Figure 14).

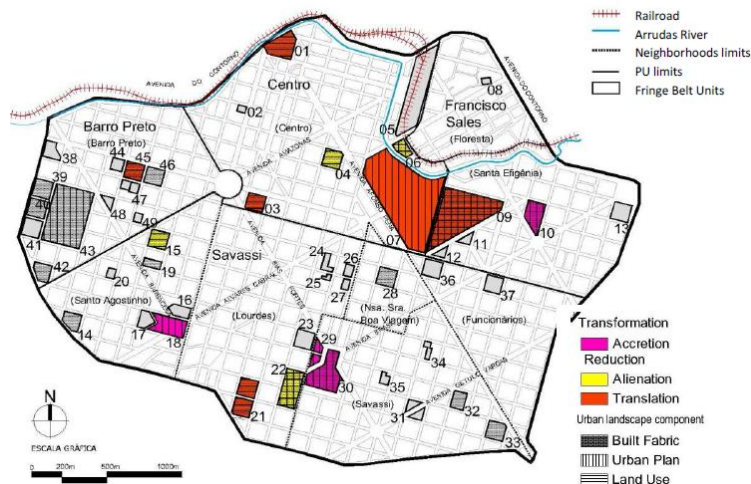

Figure 15. Transformation of fringe belt units identified within the perímetro of Avenida do Contorno (source: Simão, 2012, p.123).

The transformation of the built fabric of 45% of all fringe belts units identified in the area was justified by incentives to encourage increases in density and verticalization, contained in the Use and occupation of Land legislation in the area under study. This phenomenon is a consequence of a change in the classification of most fringe belt units, from SE-1 (Special Sector 1), or SE-2 (Special Sector 1), for ZCBH (Central Area of Belo Horizonte) or ZHIP (Zone Hipercentral). Spaces defined as special sectors and having the characteristics of fringe belts, occupied by public amenities and presenting reduced occupancy rates, were classified in the laws of 1976 and 1985. In the guidelines of the new 1996 law, most fringe belt units had their zoning changed from Special Sector to Central Zone of Belo Horizonte (ZCBH) or Hyper Central Zone (ZHIP), thus allowing greater density.

The increase in built area fringe belt units has occurred mainly in ZCBH, since, according to Caldas, Mendonça and Carmo (2008), the land use and occupation regulations proposed for the zone use a coefficient ⁴² equal to 3.0 and allow smaller side and rear clearances in relation to that permitted in the zoning of the rest of the city, thus facilitating the construction and approval of new buildings on the blocks. Despite this legal incentive, 55% of fringe belt units identified have not undergone transformation. This could be explained by the fact that most are classified as cultural assets and are protected by preservation orders and / or because of their planned and consolidated public amenity status.

Concluding Remarks

The identification and analysis of fringe belts units define the shape and density of the city, as well as, type of use and potential. These characteristics also reflect the historical period and the

⁴² Multiply the area of the land and the utilization coefficient to indicate the highest construction area on the land, adding up the total number of floors in the building.

socioeconomic conditions of urban development. Thus, fringe belt units have been identified with the aim of recognizing the shape and potential of the urban landscape of the area within Avenida do Contorno, starting with the study of the theoretical framework and the fieldwork carried out.

An analysis of the area's urban evolution reveals that the fringe belt units identified in unoccupied areas and on the edge of urban occupation, within the inner perimeter of Avenida do Contorno, constitute the IFB (Inner Fringe Belt).

Each morphological element was analyzed with a view to mapping out the transformation process of fringe belt units in accordance with the alteration of the three elements that compose the urban landscape: the urban plan, built fabric and land use. Thus the results show that 45% of the fringe belt units had a modified element, being that 100% of them manifested a transformation in the built fabric, 40% showed changes in land use and 40% modifications in the urban plan. Therefore, it can be said that encouraging density and verticalization, as in the Law of Land Use and Occupation, induced alterations in the built fabric. There is thus a clear contradiction in a law that establishes the rate of permeability, which should limit excessive density, whilst at the same time defining areas in which increased density and occupation are allowed or even induced, especially in the central area.

In addition, the type of transformation which took place was also classified as reduction or extension. It was concluded that 30% of the fringe belt units were subject to this type of transformation, 30% of them through extension and 70% by reduction. Most fringe belt units had their area reduced. The reduction in the fringe belt is the most important result of the urban transformation witnessed in the area under study, which may explain the distribution of the fragmented form of the inner belt analyzed and the remaining areas identified in Belo Horizonte. The fringe belts in the city are composed of several units that are not connected and do not form the rings recurrently identified in traditional studies on the topic. Therefore, the elements identified in Belo Horizonte have developed in a different way to those witnessed in traditional research.

In view of the importance that fringe belts represent in relation to the urban landscape and the few studies on these morphological elements in Brazil, this work has provided perspectives, which it is hoped will stimulate new studies on the theme, especially in analysis relating to the transformation of the urban landscape and its elements.

Urban morphology and architectural design in small towns. The case study of San Vito Romano

Pina Ciotoli

Departement Diap, Doctorate Draco, University of Rome "Sapienza", Italy
E-mail: giusiciotoli@libero.it.

Abstract. *This paper presents a case study of an ongoing research on urban morphology and design in small towns, following an experimented methodology (Strappa, 2013) focused on special building types, and the relationship between consolidated urban tissues and contemporary design. This methodology is applied in the case study of San Vito Romano, analyzing the place as a text, identifying the elementary structures and subsequent changes of the historical fabrics. Reading the place in different scales, territorial, urban organism, urban fabric, building (basic, specialized) we understand the formation process, corresponding to a phenomenological reduction necessary to solve the organism's complexity. Reading buildings and public spaces is substantial and integral part of the project. The specific characteristics of housing expressed by type's notion are transformed over time through continuous updates. The most important of these changes is recognizable as a specific character of Italian architecture, the increasing of basic buildings to form specialized ones. The project is based on the concept of a building as a synthesis of all these processes, so were considered the relations established over time between routes, public spaces, buildings. All this constitutes the primary structure of the project.*

Key Words: Urban-morphology, architecture, urban-design, small-towns, knotting.

San Vito Romano is a case study of an ongoing research on the historical small towns of Lazio (Italy), following morphological - typological approach (Strappa, 2013). The project, that was a part of a thesis degree, has been considered as a final outcome, in order of time, of a transformation process historically determined. San Vito Romano enjoys an excellent geographic location; it extends Prenestini Mountains and overlooks the valley of the Sacco River, lying a few hundred kilometers from Rome. Despite the favorable location and historical importance that the municipality had up until XIX century (it was the seat of the Comarca Notarile), the center of San Vito is devoid of services for citizens's active life and today presents itself as a company town. The abandon of the surrounding agricultural areas is worsening the economic and environmental situation of the area, depriving the center of the dignity that historically has always had. The study of San Vito Romano's territory is based on the idea of preserving the identity of the built, whereas the old town centre as an organism, consisting of elements in a relationship of necessity between them. In this way, the town is not treated as a museum, like any work of art to be protected.

Conservation becomes an active operation, that the current phase of a process, consistent with the historical legacy of the past, of which we can recognize the characters as training and mutants.

Reading San Vito Romano's territory we have carried out analysis on territorial and urban scale to identify several systems which spell out the reasons for the roots of the community in that place, and the "formative process" of the site. The area and the urban aggregate were interpreted according to the paradigm of the method, so we can recognize characters and potentiality of the land that have been transformed by human activity. On a territorial scale the shape has been recognized as a visible aspect of a structure transformation, where it was formed a system of bound distances of the land, the valleys and the hills upon which pseudo-ridge pathways are implanted (Caniggia, Maffei, 1979). Reading the aerial photo we've identified pathways of primary and secondary ridge. San Vito is located along a secondary ridge that

branches off from the main path: in this case, the structuring of the territory is quite common also to other historical centers. Very often the main ridge path does not host the best place to the formation of the settlement. Reading San Vito's urban fabrics was accomplished first by surveying ground plan walls and the orientation of houses along the routes. San Vito Romano's plan has been an essential tool for the analysis of routes and tissues. We have studied the wall's orientation and the houses's access along the route to understand that in the lower part of the city we can find multiple bands of continuity. It is difficult to find elements of continuity between the lower part of San Vito Romano (where we can find the old oil mill) and the higher part (with Theodoli's Castle).

This is due to the morphology of the place and to the numerous restructuring that took place during the XVII and XVIII centuries; all this has caused a shift in land which is no longer legible the old cadastral plan. So by reading the alignments we recognized the hierarchy paths of the urban fabric, to a larger scale, and within individual blocks to a smaller scale. It was also analyzed the shape of many trapezoidal buildings. The presence of trapezoidal form buildings was due to the shift of the front housing or maybe to the less importance of a matrix route. So the cadastral unit is put in a grid of paths much more complex than the last. Before planning it was important to interpret San Vito's formative process, recognizing and recovering the typological matrices. The current reading of the building and public spaces is substantial and integral part of the project, is in fact the logical premise to establish a consequential relationship between the historical and the contemporary city.

The organic form of the town undergoes a transformation in the time that obeys recognizable principles; characters transmitted in buildings, expressed by the notion of "tipo edilizio" (Caniggia, 1972) turns undergoing several changes. The most recognizable transformation in San Vito Romano is the collaboration (repletive absorption, redevelopment) to form specialized buildings (for example in the streets of via degli Orti e via di Borgo Mario). A further analysis on town's paths was carried out to understand the formative process of the fabrics and more generally of the entire town. All these examinations underline the peculiarity of a block in which was found a row house, located in a strategic area of the country, next to the Theodoli's Castle and via di San Biagio. Starting from the identification of land ownership, were assumed the formative stages of this first block; then the plan was compared to the actual and historical cartography. At the end we have studied the building alignments. The analysis of this territory and the subsequent design phase involve in dealing with archeology and the historic built. Even the analytical phase is considered as a critical moment in which to express a historical judgment that concern to the future, not only to the present or the past. So the critical operation and planning begins by reading the reality and concludes the process of knowledge, based on the notions of continuity and organization in architectural design. This develops as a congruent transformation, based on the undeniable fact that the city as a living organism, must constantly evolve to survive. It's also important to state that the design of the new took place not only through the study of primary and secondary paths, but relying on the network of intersections between the routes and the nodes, and according to the notions of basic and specialized buildings.

The projec area is very wide, includes the entire south of the country and it's characterized by different altitude. The gap of 5 m between the two paths of via Borgo Mario and via degli Orti is solved by new building's roof. This seems to continue the square in front of Porta Borgo Mario. The gap of 35 m between via degli Orti and piazza di Porta Olevano is solved either by using a mechanized lift to the inner wall of the so called "Cavone" that with a walk along the slope. The formative process has shown the importance of existing routes that has changed over time through continous updates. In fact through the study of urban tissue and paths's hierarchies we can consider via degli Orti, still in state of neglect, as a new matrix route. Tissues on via degli Orti have the same orientations, so in the past this street had to have an important role for the entire city. For this reason the road is considered as the matrix route on which developed the first cells of the project. The secondary route provides for the first building in the use of an ancient underground route that connects via di Borgo Mario with via degli Orti, and for the

second one, the so-called "palazzo", the use of an existing staircase. Another path, the so called "percorso di collegamento" takes shape as a new via degli Orti and connects the two buildings of the project. In the last phase of the formative process, the central part of the palazzo is specialized on the first level as a square and on the level below as a lecture hall. The building has been called " palazzo", to synthesize the merge process and plot amalgamation of the tissues; so the new building has been project as a urban node, a urban knotting of the paths that can form the new public space. On the second level of the palazzo we can find the knotting of the entire project; there is a square that follows the alignments and the wall warping of the ancient buildings. This square is closed to the south by a barrier, and it is outlined as node design and public space of fundamental importance for the whole town. The second building solves many problems due to the different quotes of the entire area. In fact, its cells develop along the underground route that connects via Borgo Mario with via degli Orti (in the past there were the cells of Carmelite friars and nowadays we can find the seat of municipality. On the ground zero of both the buildings we can find a "percorso di collegamento"; it is a new street designed to connect the palace with the second building. We should underline that the project has recovered and converted some existing buildings (the oil mill, Theodoli's stable, an ancient building and the fountain of piazza di Porta Olevano). In addition, all existing buildings, in particular the Theodoli's stable have defined the size of the cells used in the composition of the project. The existing buildings is in a state of abandon, although he had in the past and it appears to still have a strategic position, especially compared with town nodes. The stable is in fact close to the Theodoli's Castle, the great architectural emergency of the upper part of San Vito Romano, and to piazza di Borgo Mario. The project includes the restoration of all these buildings. Piazza di Porta Olevano is the node of major strategic importance to the lower part of town. The project involves the connection between the main road and via di Porta Olevano through a combined system of squares, rest areas and stairs. The present mill town on via di Porta Olevano has become a garden inside which penetrates the pavement of the square, directing the visitor to the seats. So we can say that the project is the last part of the analysis, and is based on the concept of building as a synthesis of all these processes.

Railway as vehicle of urban transformation. Past and present of the railway station

Kateřina Čechová

Faculty of Architecture, Czech Technical University, Prague

E-mail: cechokat@fa.cvut.cz

Abstract. *This paper aims to analyse the impact of railway development on the European city, and compare the impact it had in the middle of the nineteenth century and it has nowadays. A core question underlies the analysis and directs the paper on the morphological path: The urban form of the nineteenth century was significantly redefined by the presence of the railway in all scales (Schivelbusch, 1986 and Veselý, 2008). On the single unit level, the train station, as the object of major evidence of railway presence in the city, caused whole city structure to reconfigure, from the position of city centre to the infrastructural network definition (Krejčířik, 1991 and Musil, 2002). In the beginning of new millennium, the European railway celebrates its renaissance, despite not enjoying the exclusivity of its nineteenth century predecessor. The railway has changed significantly over the 150 years, so has the train stations. The hybrid objects, emblematic for the city, remind us remotely of the nineteenth century railway stations (Beneš and Ševčík, 2011). Back to the core question: Is there any transformative force in the contemporary nature of train station, affecting the urban structure in any way comparable to the force of the nineteenth century train stations? Is there any reconfiguration of urban patterns present in the contemporary city, that can be granted to the railway station of present times? The urban transformation is illustrated on several case studies, such as Prague Masaryk station, London King's Cross and Vienna Hauptbahnhof.*

Key Words: Railway, train station, urban transformation, urban structure

Introduction

If there was one single greatest innovation of the nineteenth century, responsible for major development of the society, it would probably be the railway (Powell, 1994). The effect of railway invention and development was ubiquitous, by no means limited to urban development. Through the railway, the technological progress entered everyday life of ordinary people and made them believe in the power of modern science. Railway brought completely new sense of speed, not achieved by any of the vehicles then known, causing passengers to feel overwhelmed with new perceptions (Schivelbusch, 1987). It was also railway which accelerated the spread of revolutionary liberal thoughts throughout Europe, and as many believed, the railway had a power to unify nations (Schreier, 2010). Spread of railway made travelling affordable for masses, contributing to growing mobility and its democratization (Hons, 1961).

The core of this paper will nevertheless focus on the effect of railway development on the transformation of urban structure. The sum and substance is placed on the main passenger railway stations of European metropolises, their role in this process, and transformation of this role comparing the second half of the nineteenth century with current situation. First section analyses the aspects of formation of a modern metropolis, assigned to railway development, in the second section the current role of railway stations in the redevelopment of urban fabric will be tackled.

The heritage of past railway forces as well as their current potential has set the ground for numerous urban regeneration projects, being realized all over Europe on disused railway sites. For demonstration of past and present transformative forces of railway in the cities, three such locations with existing projects or realizations were chosen:

London has an exceptional position among European cities, since the end of seventeenth

century the largest city in Europe and first capital adopting the rail roads. Their quantity and complexity creates highly challenging situation concerning contemporary railway sites regeneration. On King's Cross station, the best practice project has been under construction since 2008.

Vienna on the other hand was rather peripheral metropolis in the nineteenth century, representing a "model" middle European city, sharing common history and cultural background with cities such as Prague and Budapest. Vienna is currently adopting several ambitious railway regeneration projects, including Vienna main station.

In Prague, none of the so far existing projects of railway regeneration has been launched yet, which opens up an opportunity to get inspired by foreign case studies, dealing with similar issues formed by railway presence. The exemplary case is the Railway station Prague (in the text referred to as Masaryk station, its contemporary name), the first and most centrally located railway station in Prague.

Railway in the nineteenth century

The earliest motivation for the construction of railways was transportation of raw materials - wood, salt and stone, later on, with the progress of industrial revolution also coal. Moreover, railway itself stimulated production through demand of further coal, steel and mechanical engineering manufacture products. Private railway companies, investing in the first railway lines, were usually consisting of local businessmen, bankers and industrialists, especially the latter were pushing such railway route, serving their estates, or securing their profits. The passenger transportation was secondary in the first decades of railway development, which started to change in the middle of the nineteenth century, when passenger transport spread.

The environment conditions were also a decisive factor for route choice: Since the railway gives the highest performance on minimal ascent, with carriages moving on smooth, level, hard and straight surface (Schivelbusch, 1987), the railways followed rivers and valleys, if possible. The railway could adapt to the existing environment only to a certain extent, beyond that, the environment was about to adapt to the railway. It cut through the cities and landscape, with new works of engineering such as embankments, cuttings, viaducts or tunnels, the less valuable structures had to give way to rail roads. According to Veselý (2008), railway represented autonomous technical system of objective parameters, layered over the system of everyday randomness. The conflict of these two systems, causing the barrier of movement and development, has represented an especially difficult task for engineers and architects since the first train reached a city.

Locating the first railway stations

Apart from the technical and environmental limits, the price of land was in the foreground, since most of the rail roads were developed by private companies, while each of them constructed their own railway station including all facilities. The first railway stations of the European capital cities were hence almost exclusively terminal stations, rather than single through stations (Nilsen, 2008), placed on the outskirts of the city. Sparse settlements or completely unbuilt, cheap land, was preferred.

For illustration of the early railway stations' location, there are two figures (figures 1 and 2), capturing urban structures of Prague and London in the similar historical moment: The railway node was established for long ahead, yet the urban growth had not yet set the hottest pace. This historical moment came earlier in London (1845), later in Prague (1870).

Figure 1. Schematic map of Prague, around 1872.

Figure 2. Schematic map of London, around 1845.

The middle nineteenth century Prague was built up within the city walls - of baroque construction but of the fourteenth century footprint (Fig.1). The city area was as large as of the medieval town, so was the urban structure and street network. The location of railway station was found in a curious position, the passenger part within the city walls in Prague, whereas the facilities outside the walls, in the rapidly developing neighbourhood of Karlín. Six new gates connected both parts of the station. The site of Prague station was previously used as flower and vegetable gardens and execution ground, later as military hospital and popular pleasure restaurant (Schreier, Kofroň and Sosna, 1995). The available inner city spatial reserve, a sort of inner periphery of the walled city, enabled this rather curious location, in contrast to Vienna, where the stations were located just outside the city walls.

London was developing in a different way than the middle European cities. Before the arrival of first steam locomotive, the oldest district of London – the City – was already surrounded by industrial quarters and working-class dwellings districts, such as Spitalfields, Whitechapel or Southwark, which developed in reliance on the river Thames and numerous canals. By contrast, in the west side of London, to the north and east of the district of Westminster, the more affluent residential quarters were built in the eighteenth century. This social distribution had an enormous effect on the location of the first railway stations. Whereas on the West, the railway stations were located on the outskirts, behind the city structure, in the eastern part the railway stations were built on the perimeter of City district, deep in the city structure, cutting through the working-class neighbourhoods (Figure 2) (Schivelbusch, 1987). The purchase of land for the railway station construction was easier in the less-affluent districts, yet according to Kellet (2007), the expenses for the British railway stations were almost devastating, making it the decisive factor for choice of the site.

City expansion

During the industrial revolution, European cities were facing immense influx of migrants, feeding the growing industry. Even the least advanced European cities launched demolition of their city walls (Prague: 1874, Vienna: 1857 old city wall, 1894 Linienwall), hence the last barrier of the city expansion was gone. The effect of railways was imminent: Factories were settling behind the city on the available land, supply of raw materials and coal was enabled by railway. Newly incoming workers were settling in the working-class districts emerging nearby, or in the unkempt central districts. Introduction of affordable commuter train determined the patterns of suburban development, especially for higher classes, repelled by polluted air and dirt of the city.

According to Brigs, 1968 and Musil, 2002, railway was unambiguously a concentration force, bringing population to the vicinity of stations and standing in the background of rapidly growing cities. Nevertheless, concerning single cities and new perception of space and time (Boyer, 1996 and Schivelbusch, 1987), the cities of late nineteenth century were spreading along the rail roads far beyond the traditional city core. The city centres rapidly depopulated, fell into disrepair or transformed into business districts, whereas new residential settlements of lower density (garden cities) were far beyond the city. This familiar description corresponds to the image of late twentieth century western metropolis, however attributed to the development of automobil industry. Nevertheless, there is a link between future urban sprawl and “Zwischenstadt” culture (Sieverts, 2003) and the development of railway.

London, the first world city of the age, had quadrupled the number of its inhabitants between 1800 and 1900, with over 4 million inhabitants in the beginning of twentieth century. As the first industrialized city, London’s congestion, pollution and lack of greenery was most advanced, so was the development and popularity of living in suburbs (Janata, 2009). Compared to London, Vienna and Prague were conservative cities, expanding later by the end of the nineteenth century, after the demolition of city walls.

The railway stations brought dynamic to the development of inner districts. The previous node of passenger transportation, the stagecoach inn, could by no means compare to the new infrastructural node of railway stations with immense volumes of people and goods flowing in and out (Schivelbusch, 1987). This newly experienced intense concentration in the vicinity of railway stations was attracting certain functions (retail, business), while repelling others (residential or smaller workshops). The smoke of steam engines made buildings black and sooty, yet the bustling atmosphere attracted many cafés, restaurants and hotels, leaving the traditional city centres behind.

First structural changes of the street network were conceived in order to cope with the intense traffic, incompatible with narrow winding streets of inner districts. In smaller cities with through stations located on the outskirts, new street, connecting station directly with the city centre (so called “Bahnhofstrasse”, railway station street), was placed. Such streets are legible in the urban structures of cities such as Zürich or Weimar, until nowadays serving as pedestrian and public transportation shopping and business streets. In contrast, such streets had never been established in the urban structures of Prague, Vienna or London (Vorrath, 2010). Some streets may though play similar role, connecting railway station with the city centre, such as Mariahilfer Strasse, connecting the Western Station with the centre of Vienna. For dispersion of passengers and easier access of horse-coaches, spacious plazas were constructed in front of some stations.

Railway expansion

The spatial requirements for the railway operations were growing in the course of the nineteenth century, mainly the freight transportation required new storehouses and transit sheds. The North

railway station, supplying Vienna with coal and salt grew from initial 2 ha site in 1837 up to 96 ha by the end of the century. That made it as large as the central city district (Vorrath, 2010). In King's Cross, the facilities of first Coke and Gas Company and storage facilities for grain, potatoes and coal created an area of 27 ha (King's Cross Central Limited Partnership, 2014). According to Kellet (2007), up to 10% of central land in London was owned by the railway companies.

Apart from the storage facilities, usual equipment of each railway station consisted of waterworks, locomotive shed, and marshalling ground, shunting yards and sidings. The passenger equipments were expanding as well, with new tracks being added and halls expanded.

The railway stations started to create large "voids" within the cities - vast inaccessible areas, splitting newly formed neighbourhoods and making establishment of efficient circulation network impossible. English idiom "wrong side of the tracks" represents the spatial and social division railway tracks formed in the cities.

In 1960's, Masaryk station had nowhere to expand in the vicinity, so it established repair and maintenance sheds and marshalling yard in Holešovice - Bubny, implanting barrier into another location in Prague. The existing location of Masaryk station proved to be troublesome for the first time after the city wall demolition, when the "Ringstrasse" concept – representative boulevard with public buildings and parks, inspiration from Vienna – was impossible to implement. National Museum, Opera house, new railway station (today Main Railway Station Prague) were built along the former city wall, planting the seed of future north-south communication. The inclusion of the railway sites of Masaryk Station into the urban network as a part of this communication has been an architectural issue since the 1910's (Fig.3) The purely technical solution, a construction of elevated highway over the railway sites, realized in 1980's, can not be considered as an adequate answer to this complex and long-standing challenge (Figure 4).

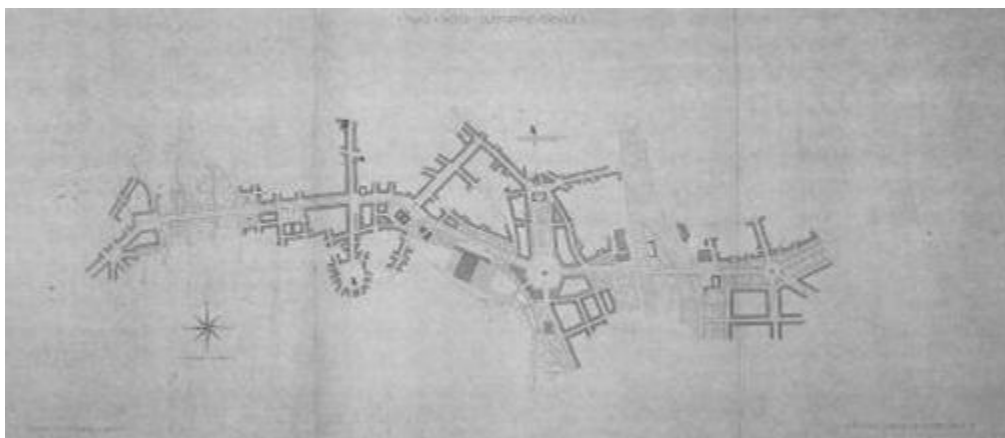

Figure 3. Proposal of north-south connection, with main square on the place of cancelled Masaryk station. Designed by architect Kutchera, the Prague Planning Commission from 1942.

Infrastructure and flows

Travellers and commuters used to cause regular congestions around the stations. The key challenge of the age was to redistribute the enormous volumes of people and goods across the city. The connection of railway stations with the city centre, with the industrial districts as well as with each other was essential.

New public transportation systems were set, first of horse-drawn buses (omnibuses), later horse-drawn trams, replaced by electric tramways by the end of the century. Freight was transported on horse coaches. Those first public transportation lines were nevertheless avoiding

railway stations, prolonging the transportation problem. Also the capacity of such systems, often operated in the street network of medieval cities was soon not sufficient enough.

Figure 4. Photography of Masaryk station railway site, view of elevated highway.

The railway station North in Vienna was served by 3 000 horse coaches a day in 1850's (Vorrath), balancing on the edge of collapse. In Prague, what we know as Masaryk station, was for a long period the only railway station in the city. Rapidly growing industrial districts in the outskirts of Prague were mostly cut off. Transporting the new railway carriages from the Ringhoffer factory in Smíchov, one such district, to the Masaryk Station in Prague on the horse carts was an all-day-long operation, jamming traffic in the whole city centre (Hrůza, 1989).

There were first attempts to connect the single termini through railway lines. These connecting lines remained mostly insufficient in their capacity, facing the demands claimed by the twentieth century traffic. In Prague, the construction of railway node was finished in 1882. The new through Main station (back then Franz-Josef Station) was constructed and new Smíchov terminus was connected with the network. Only Masaryk station, the first railway station in Prague, remained unconnected with most of the network.

First experiments with underground railway were carried out in London with first metropolitan system from 1860's facing the challenge of separated railway stations, spread across the city. First section of the „tube“, connected railway stations Paddington, Euston, St.Pancras, Farringdon and Moorgate, and as such set the example of infrastructural network with multi-modal nodes. The first underground line was later extended and created the „Circle“ underground line, finished by the end of nineteenth century.

Railway station buildings

Before the power of railway was recognized, the very first passengers' railway stations of 1820's and 1830's were plain utility sheds, adjacent to the more important freight stations (Powell, 1994). Yet the principal expression of the railway architecture of great passenger stations, such as London St Pancras or Gare de l'Est in Paris was definitely established by the middle of the nineteenth century. The grandeur of the railway stations was partly inherent by their size, given the volumes of passengers handled in the stations. Nevertheless, another aspect was the representation, reflection of their importance.

The typology also evolved, the arrival and departure buildings started to be constructed separately, the train halls were covered by innovative roof constructions of glass and steel, inspired by Joseph Paxton's Crystal palace in London, the house of Great exhibition in 1851. Monumental facades of the passengers' halls corresponded to the most glamorous civic buildings of the era. The architectural style was turning to the glorious past, with classicist, neo-renaissance or neo-gothic decoration disguising the industrial nature of the buildings (Schivelbusch, 1987).

The cityscape, until recently dominated by the landmarks of castles and cathedrals, gained new monument. Besides theatres, museums and government buildings, the railway stations were one of the most spectacular buildings of the time.

In terms of Aldo Rossi's "The Architecture of the City" (1984), the railway stations of the nineteenth century are primary elements of the city structure – objects capable of accelerating the process of urbanization, they are able to characterize the process of spatial transformation, often acting as a catalyst. Objects of impressive form, capable of structuring the city (1984, 18).

Contemporary railway station

In the course of the nineteenth century, railway worked as unprecedented force in the re-configuration of city structure. The heritage of this force is interwoven into complex reality of current cities: large bleak sites of disused railway facilities as well as magnificent buildings of railway stations, places extraordinarily well connected with the network of public transportation as well as barrier-like object, separating whole districts.

Large railway sites, busy with railway operations, belong to the past. The freight market has changed with the spread of electricity, majority of goods is no longer transported through railways and facilities for steam operations are not in use any more. Rationalization of the operations enable to diminish the marshalling yards, the unified and well organized railway node enables the railway companies to share common facilities efficiently.

The disused railway sites are enormously large and valuable. The price of the land is in the foreground once again. What used to be a periphery behind the city walls in the beginning of the nineteenth century, is within a perimeter of the wider city centre 200 years later. The location of the railway stations represents an opportunity to reuse the sites in a way to extend the functions of the city centre, or set-up a new centre in a derelict, neglected or just fragmented neighbourhoods. To minimize the disused areas, upgrade the infrastructural network and optimize the transfer options, integrate the site to the urban structure of the neighbourhoods, create local or city-wide landmark with urban functions and forms - the ambitions of contemporary redevelopment projects are high. How do London and Vienna meet their ambitions, and what kind of challenges would Prague face in the future?

Location of the railway station and city redevelopment

The process of city expansion, triggered by railway in the last third of nineteenth century, and accelerated by the automobil in the twentieth century had come to the point of unsustainability. Depopulated city centres, settlements sprawling into the free landscape, diffuse settlement structure, skyrocketing energy consumption, dependency on private cars and rising costs of public infrastructure, all that has alarmed governments all over Europe. With over two thirds of the Europe's population living in the cities and towns, the demand of sustainable urban development is getting strong. In the Europe 2020 policy framework, between 2007 and 2013 EU invested about 21 billion EUR in sustainable development projects, such as rehabilitation of industrial sites or urban regeneration projects (European Commission, 2013). Large sites of railway brownfields represent such trend of reuse of well connected inner city reserves.

Vienna adopted a truly strategic approach in railway sites redevelopment, including the city rail (S-Bahn) and underground (U-Bahn). Austrian regeneration program for railway stations, so called "Bahnhofsoffensive" (railway station offence) was launched in 1997 with six railway station areas from Vienna being included, sharing the same project guidelines: Westbahnhof, Nordbahnhof, Hauptbahnhof, Heiligenstadt, Wien-Mitte and Hütteldorf. The first Austrian "railway city" project, development of Westbahnhof, was finished, meanwhile the projects of Nordbahnhof (96 ha) and Hauptbahnhof (109 ha) have begun. Outside the regeneration program, the multi-modal terminus Praterstern has just been finished and the prospective Nord-

West Bahnhof development (44 ha) will begin within few years (Vorrath, 2010).

In London, there has been projects of railway stations redevelopments realized since 1980's, such as Broadgate/Liverpool Street or Ludgate, yet without any overarching framework or policy. The development was primarily a way of raising money for railway operations in times of cut back in public funding with an enormous pressure on commercial appreciation of the site (Bertolini, Spit). Currently the most ambitious of all redevelopment projects is the regeneration of King's cross – St Pancras terminus with implementation of high speed international connections and Thameslink line, along with mixed use development (29 ha).

All over Europe, various projects of railway station areas have been launched or finished, such as Euralille in Lille, Zuidas Amsterdam, Zürich Europaallee, Basel Euroville, Winterthur Sulzerareal, Berlin Hauptbahnhof, Paris Rive Gauche - Gare d'Austerlitz, Milla Digital in Zaragoza or Stuttgart 21. The emergence of new quarters is happening again, and those quarters rise on the former railway sites.

In Prague, there are currently three large central railway brownfields, attached to existing railway stations: Masaryk station (19 ha), Holešovice-Bubny (76 ha) and Smíchov (179 ha, including large industrial regeneration zone). Currently, there is no comprehensive strategy for redevelopment of these zones, neither an effective tool, restricting greenland development and supporting brownfield development. In past years, larger parts of the property were sold to private investors, who initiating single projects and negotiating their approval with city representatives. According to Fragner (2012), urban development project in Prague are mostly a good way to patch up the holes in the city's budget.

The Masaryk station area currently borders three districts: the medieval New city of Prague and two industrial and residential districts, developed in the nineteenth century, Žižkov and Karlín. All districts has been going through massive redevelopment since 1989, in case of the latter accelerated after the devastating flood of 2002, making it one of the most progressive areas of Prague. Complicated topography, rail and vehicle infrastructure, and heritage protection all play role in the separation of these three districts by the Masaryk station area.

Design tasks – permeability, accessibility, integration

On one side of the project there is upgrade of infrastructure: advance of technology made trains competitive on medium-length journeys with air-travel (London-Pars) as well as with automobil (regional connections). Due to the optimization of transfer options, railway nodes are equipped with new multi-modal terminals, including metro lines, old railway stations disabling trains to run through are being replaced by new Main stations.

Another part of the project is the regeneration of railway brownfield, its integration into the surrounding urban fabric and establishment of new connections. In order to eliminate the barrier effect of the railway station and its facilities, urban design tools elaborate on the usual height difference of rail road and surrounding environment, using various forms of sunken plazas, elevated rail road, ground floor passenger halls, bridges or underpasses.

In the main station of Vienna, the whole volume of tracks is elevated, and the ground floor is used as main space for passengers, replacing passenger hall. It is a wide corridor, underpassing the width of six platforms, connecting two squares on both side of the station, with entrances up to the platforms, to shops, to the underground and S-Bahn stations. This spatial configuration also enables existence of regular underpasses, albeit rather long, in the continuation of existing street network.

Among many projects under consideration, some still use rather dated design of mega-structures, inspired by the optimistic 1960's, when the belief in strong, technical solutions was ubiquitous. Nevertheless, the solution as such was available much later, and these projects have often survived up to recent times. Such case was the 1960's to 1990's proposal for Zurich Hauptbahnhof, consisting of large building, spanning over the platforms and railway tracks in full width. Beside being a demanding, overly expensive structure, the design considered demolition of existing historical railway station (Wolff, 2012).

The urban design of King's Cross (design by Allies & Morrison and Porphyrios) has been extensively evaluated by various city bodies in terms of its accessibility and integration. The resulting scheme proves progress in overall accessibility, with focus on the rich network of public spaces, from the generous Granary Square to the modest walk along the Regents Canal, outdoor plazas as well as indoor halls in the Western Concourse. Open space is formed by the newly designed buildings, which are in their shapes, scale, frontline corresponding to historical pattern of the site (Figure 5) (King's Cross Central Limited Partnership, 2014).

Figure 5. London King's Cross urban pattern.

King's Cross project shows several other trends concerning the transformation effect. "The best connected location in Europe" (Argent, 2005) does not mean the dirty infrastructural node – in fact, most of the facilities, such as six metro lines, including new Thameslink, are buried underground and hence do not affect the aboveground urban structure. The new underground world provides passengers with shopping galleries and various services. Another trend is the regeneration beyond the reach of concrete site – the King's place, Regent quarter, British library or The Francis Crick Institute, all has been developed the project started, with a positive effect on the formerly dilapidated neighbourhood.

Future development of Masaryk station in Prague will have to face several serious facts, concerning accessibility and integration: re-connection of Karlín and Žižkov districts, integration of elevated highway, cutting the site in half, and infrastructural solution of the railway node. Masaryk station is the most busy railway station in Prague for regional connections, yet with limited future potential: the railway network configuration enables only connections to the east and north, avoiding the Main station. Past projects of redevelopment were considering several options: expanding the operations when introducing new Airport line, keeping only the existing operations while arranging the pedestrian connection for transfers on the Main station, reducing the station area in order to fit in the network, or complete cancelling of the operations (Novotný, 2007). Various aspects have been debated, such as foundation of a representative central city square, an idea regularly revived since 1930's (Fig.3), or construction

of city railway tunnel, double storey Main railway station and closing of the Masaryk station (SUDOP, 2011).

In spite of unclear future, the railway area and its surrounding is not sleeping any more. Florentinum, a large office building, overlooking Masaryk railway station and exceeding the height of surrounding buildings for about three floors, has just been opened in spring. The developer Penta (joint owner of the railway station property) and architectural office CMA, offer 49 000 m² of office space, shopping passage and piazza with garden, advertised as new public space. This might seem parallel to the strategy of London, nevertheless, the result is maximization of profit from the surrounding area before conceiving the overall future development. This intervention means insertion of a new larger scale of urban fabric, most likely anticipating urban development, intended by developer. (Fig.6)

Figure 6. Prague Masaryk station urban pattern.

Railway station buildings

Over the past decades, centrally located railway stations of European capitals became vulnerable to redevelopment. Before establishment of monument protection for the industrial and infrastructural heritage, several railway stations were demolished, with Euston station in London, the first grand terminus, being the exemplary case (Powell, 1994). In Vienna, non of the six original termini remained. The splendid railway buildings of the past were replaced by modernist utility objects, such as new Euston station in London (finished in 1968), South station in Vienna (finished in 1961), or Smíchov station in Prague (finished in 1956). The deep contrast between the buildings of the past and of the contemporary modernist ones caused severe public protests, resulting in the remaining grand stations of the nineteenth century being classified as historical monuments, despite with protection mainly limited to passenger and train halls (Nilsen, 2008).

For various reasons, some of the historical railway stations has been transformed for another

functions – they were either not meeting the requirements of contemporary railway operations, or the railway network was remodeled in another way. For example, North-West station was used for exhibitions and events, in 1920's a „snow palace“ was set in there with a ski run and inclined plane for ski jump with artificial snow. Since 1989 Parisian Musee d'Orsay has been established in the building of former railway d'Orsay, while Atocha station in Madrid was transformed into tropical garden.

Another railway stations of the past go through conversions – in order to become the railway stations of the present, with extensions or new railway buildings added to complement the services, such as shopping mall, cultural venues, facilities for commuters, sweetening the transit between various modes of transportation or transforming the railway station into a destination (Namiki, 1995). New railway stations are truly multifunctional objects, with rail travelling being only one of the range of functions provided. The once strong statement of monofunctional monuments – railway stations – has gone for good.

In some cases, monofunctional buildings evolve into hybrid objects, containing the world in itself, with privatized public space and with functions not adding up, but merging (Ševčík and Beneš, 2011). Such objects are big in terms of Koolhaas' theory of bigness (1993): their envelope does not communicate the inside, there are various autonomous parts, uncontrollable of single architectural gesture, but is still committed to the whole (Koolhaas, 1993). Large part of the terminals takes place underground, without really revealing it through the urban structure visible on the surface.

Reconstructed railway stations often aim for striking aesthetics and expressive form, along with galleries, museum, airports and shopping malls, they are on the mission to upgrade the image of the metropolis and improve its competitiveness (Ševčík and Beneš, 2011). Parallel to the nineteenth century train halls, the contemporary train sheds and canopies became popular landmarks, in contrast, the passenger halls as such are sometimes even omitted. The case of Vienna Hauptbahnhof is symptomatic, the passenger hall is a mere corridor, whereas the roof, diamond shaped steel and glass structure covering the platforms, was given the most attention of designers and engineers (Fig.7) (ÖBB-Infrastruktur AG, 2014). In these terms, for many architects the most Inspirational is probably the work of Santiago Calatrava, who has been shaping the infrastructural landmarks of European cities since his 1990 project for Zürich Stadelhofen railway station.

Figure 7. Vienna Hauptbahnhof, underpass and iconic roof design.

St.Pancras international and King's Cross development area show the way of creating space of various rich forms. The Iconic red-brick pseudo-Gothic building of former Midland Grand Hotel from 1860's and 1870's is forming the main facade of St.Pancras International towards Euston road and one side of the King's Cross square. Another side of the square is dominated by Western Concourse, newly constructed steel and glass canopy by John McAslan + Partners, extending the passenger hall of Kings Cross station. St Pancras was recently extended by a large hall of high speed international connections of rather generic design. In the King's Cross area

redevelopment, about twenty historical monuments has been kept and integrated into the scheme: landmark buildings such as The Granary building, conversion of former wheat storage by architect Stanton Williams, hosting The University of Arts London – Central Saint Martins, voted the “world’s best higher education building” in 2012 (University of the Arts London, 2014), along with ordinary utility buildings of the past, such as canopies for unloading of goods (King’s Cross Central Limited Partnership, 2014). This strategy helps to keep the memory of the site, integrating the rich railway past into the current city fabric.

Masaryk station is located within the Prague Heritage Reservation, with railway station building being the last great railway station in Europe of the first generation buildings, constructed before 1850 (Zeithammer, 2009). Pseudo-Renaissance building was designed by engineer Anton Jüngling in 1845, the objects were going through extensions in 1870’s, with corner restaurant and glass canopy spanning over the platforms, and facilities building such as locomotive shed and workshop being constructed in distant position. The railway buildings are under protection as national monument since 1958, the former locomotive shed is nowadays conceived for foundation of Railway museum, part of the National technical museum. There is a chance that these buildings will remain on the site as a part of the future urban development, keeping the site memory and creating landmarks of the area in the same way we can observe it in King’s Cross.

Conclusion

Schivelbusch (1987) is writing about the gigantic brushstroke of the early railroads, cutting the nineteenth century cities’ urban fabric. The works of contemporary architecture and engineering gives the opportunity to almost erase the legible traces of this brushstroke. Voids are disappearing, urban structure interconnected, bleak sites revived. From the city structure interventions caused by railway, seemingly only the positive ones remain.

On large-scale, railway serves as a tool to re-configure the cities, enabling re-establishment of sustainable urban patterns. Railway enables to regenerate the inner city districts, while providing place for new development, and limits suburban development to areas well connected to the city. This tool may or may not be used, as observed in case studies.

In the framework of single cities, there are mostly urban design tools available for overcoming the barrier-effect of the railway sites, establishment of new connections and integration of the newly developed land into an urban fabric. In the best practice cases, the regained confidence of the contemporary railway station is signalized by expressive architectural features, yet incorporating old memories of early railway times into urban schemes.

In Prague – all these tools to make railway stations prominent, though positive, transformative force, have not been fully employed yet. The development is in the point, where much of the potential could be wasted by ill-conceived implementations of urban development, but also where a lot can be achieved by using wisely the transformative force of railway.

The impact of Lisbon's subway development on *Avenida da República*

Mafalda Teixeira de Sampayo, Carina Silvestre

Departamento de Arquitectura e Urbanismo, ISCTE-IUL ISCTE-IUL, Av. Forças Armadas, 1649-026 Lisbon, Portugal

E-mail: mgts@iscte.pt, carinasilvestre4@gmail.com

Abstract. *In an environment of political regeneration, Lisbon expansion during the XX century is marked by the “Avenidas Novas” (new avenues) project. In this work we show how the development of the Avenida da República is affected by the development of the Lisbon subway. The opening of a new subway station is transformative event that has potential impacts on the development of different sectors and of the growth of the city. This work was done by in several steps: (i) critical reading of works that focus the space and time of the object of this study; (ii) identification and analysis of several specific moments of the growth of the Avenida da República through urban cartography and (iii) assessment of the urban form of this avenue through a comparative analysis of the results.*

Key Words: Urban design, morphology; urban form, Lisbon subway, Avenida da República

Introduction

This work is to be considered in the context of a larger research project. Starting from the hypothesis that the mass transportation system of the subway acts as a driver of the transformations of the urban fabric this work presents the case study of the *Avenida da República* in Lisbon in the context of its three main subway stations. We aim to examine the evolution of this main boulevard in terms of its buildings, taking into account the several crucial development periods of Lisbon's subway system.

How can the transportation systems, namely the subway system, condition the development and growth of the city? How will it interfere with the social and economical factors of the city policies? How does the subway change the urban fabric, connecting (or eventually disconnecting) different city areas? These are some of the questions that this study aims to answer.

The subway constrains and promotes simultaneously the territory development. It is in itself a process of urban renewal. The subway growth gives rise to new forms of centrality, acting as an attractor for new city usages, according to the location of subway stations. This role of the subway can define different typologies, with places suited for services, commerce, and office buildings, residential, among others.

This research aims to contextualize the city growth at those dates with the subway expansion. In the inauguration date of the subway (1959) the stations of Entrecampos, Campo Grande, and Saldanha open their doors to *Avenida da República* forcing changes in the boulevard uses and stimulating its growth. The development of this subway line, the relative importance of its stations would see changes in their centrality that would then have several implications on the boulevard identity, mainly in buildings facing the boulevard.

Objectives

The main objective of this research is to study the changes suffered by *Avenida da República* through time, taking into consideration the crucial periods of the development of

mass transit systems in Lisbon, namely the transformative implications of the construction of the Lisbon subway.

This was accomplished also with the fulfilment of secondary objectives in the study of *Avenida da República* such as: i) the Identification the buildings that are still intact since their construction; ii) the identification of the architects that took part in the different phases of its growth; iii) the evaluation the impact of the construction and expansion of the subway of Lisbon; iv) the Identification of the reasons for the demolishing of buildings seen between 1959 and 2014.

Related Work

There have been several methodological contributions to the study of the city of Lisbon, and in particular for the study of the new avenues (*avenidas novas*) and the *Avenida da República*. Those contributions are based on different approaches ranging from urban history (Dá Mesquita e Serrano, 2007; Silva, 2006), to urban design (Sampayo, 2003, 2011, 2012), to infrastructural analysis and network analysis (Rodrigues and Sampayo, 2009; Derrible, 2012).

Dá Mesquita and Serrano (2007) in “Construção Moderna” performed an extensive analysis of the different aspects that are involved on the development of the city plan in the early XX century, which are crucial to the present study. The authors state that in this period the city development had little dependence on the city plan once the power of decision belonged to the owners. Thus, they describe that the urban intervention is regulated by “special solutions whose technical and strategic value superimposes the construction of an image of the city established earlier - translation by the authors” (Dá Mesquita e Serrano, 2007, p. 69).

Silva (2006) presented the new avenues as “an efficient picture of Lisbon development in the latter part of the XIX century - translation by the authors” (Silva, 2006, p. 127) referred to the industrial era. Accordingly to the author the Parisian-like Boulevard was the main reference to inspire the connection between *Campo Grande* and the ancient *Passeio Público*. However, she states that the quality of the architectonic solutions adopted was inferior when compared to the great quality of the urban project (Silva, 2006, p. 127). This fact is still visible today on the buildings along the *Avenida da República*.

Previous studies by Sampayo (2003, 2012) analysed the urban form and its public space, showing that Lavedan’s plan permanence law is observed in several urban locations through out history. The new avenues plan is one more example where this can be observed.

In Derrible (2012) work entitled “Network Centrality of Metro Systems” the author studies the subway systems of several cities using a network analysis based methodology, namely in terms of traffic. For this the author analyses the *betweenness* (Freeman, 1977) of 28 subway systems across the world to understand the regularities and trends in centrality as a function of the subway system size.

Rodrigues and Sampayo (2009) showed the role of Closeness and *Betweenness* in the subway of Lisbon in the period spanning from 1959 to 2009. The authors produced a comprehensive analysis of the different stages of the subway expansion measuring the network properties of interest for the study of the urban form. This work expands the work of Rodrigues and Sampayo (2009) by extending the study to the upmost recent transformations of the subway network.

Methodology

The methodology used for this research is based on four steps: i) research in archives for material gathering; ii) production of building report cards from gathered material and direct observation (when possible); iii) graphical analysis of the cartography and maps, and iv) data

interpretation.

In the archives research (Arquivo do Arco do Cego, Arquivo Fotográfico e Arquivo Intermédio da Câmara de Lisboa) several maps were identified and dated to different periods. A comparison between these maps proves the evolution of the buildings through out the years.

The building report cards were produced for the buildings of *Avenida da República*. These include: i) images of the built structures before the building and of the existing ones, ii) dates of construction, demolition and reconstruction, iii) functional description of the building, iv) number of floors and v) author of the project.

These report cards allowed the construction of a historical timeline about the evolution of the boulevard. This timeline highlights the changes that it suffered through its history.

The graphical analysis of the existing cartography was done using software systems for Geographical Information Systems (GIS) and Computer Aided Design (CAD). The usage of these two software programs helped in the understanding of the *Avenida da República* growth over time. Both software systems allow for complimentary analysis of the boulevard allowing a quantitative analysis of spatially defined data.

In this study of the development of *Avenida da República* four dates were taken into particular consideration: 1908, 1950, 1970 and 2014. i) 1908 corresponds to the initial phase where the initial plan of the city blocks is defined by the construction of the main avenues that support the plan and the initial constructions are built; ii) 1950 is the phase just before the start of the construction of the subway in *Avenida da República* where one can observe the big developments since the 1908 city plan; iii) 1970 in this phase, after the subway construction in the avenue, its when the roads, sidewalks and some city blocks suffer some minor rearrangements; finally iv) 2014 corresponds to the present situation, where all city blocks are fully occupied.

In the data interpretation step, the analysis was aided by two software packages: GIS and visone (Brandes and Wagner, 2004). GIS was used for spatial quantitative analysis of the maps and visone was used for the topological analysis of the network of the Lisbon subway system.

This methodology allowed the confrontation of the data obtained for the evolution of *Avenida da República* and the subway expansion.

Avenida da República

The growth of Lisbon in the XIX century arrives on a later stage when compared to other European capital cities.

The idea of planning the modernization of Lisbon begins to take shape in the latter part of the XIX century. In 1864, it is created the Ministry of Public Works (*Ministério de Obras Públicas*) with the aim of creating a plan of general improvements. However, that plan ends to be formulated by the municipal chief engineer Pierre-Joseph Pézerat (1800-1872), in 1865, entitled “*Mémoires sur les études d’amélioration et embellissement de Lisbonne* - translation by the authors”. On this work Pézerat describes “a strategy to apply in Lisbon similar to the one adopted in Paris by Haussmann - translation by the authors” (Paixão, 2007, p. 107), in which are included plans for a sewerage system and water supply plan, with the main purpose of “renewing the urban design of the city and of improving the existing infrastructures translation by the authors” (Paixão, 2007, p. 107). However, the proposals presented by Pézerat would end by being rejected by the city council of Lisbon, “who considered them unrealizable and utopian in a time when the city council was dealing with economic difficulties - translation by the authors” (Paixão, 2007, p. 107).

With the need of expansion came the necessity of a new urban design plan for Lisbon. Consequently, it was asked to Frederico Ressano Garcia to formulate the expansion plan. Ressano Garcia finishes his studies in engineering, in 1869, at the École Imperiale des Ponts et Chaussées of Paris. He returns to Lisbon and starts working at the city council as a municipal

chief engineer using the work of Pézerat as a starting point.

In 1888, it initiated the expansion of the city from the Ressano Garcia's plans with all the ideas inherited from Paris. The expansion project presented had the main purpose of congregate the previous plans in order to create a fluid and fast connection to the river. It also intended "to endow Lisbon of new residential blocks with efficient internal articulation and capable of stimulating the external environment - translation by the authors" (Silva, 2001, p. 60). The plans correspond to "an area defined by the topography and by the configuration of a future block - translation by the authors" (Lamas, 1993, p. 221). According to Ressano Garcia, the narrow streets of the ancient Lisbon and the interior of the blocks were poorly ventilated and illuminated.

In the planning Ressano Garcia decides to include some hygienization ideas with emphasis laid upon the regularization and enlargement of streets, the integration of a sewerage system and a water and electricity supply system, and the plantation of trees. The latter consisted in long central bands of trees along the avenues so that the public sidewalk could be adapted to the residential area around.

The foundation elements used in the creation of a new image of Lisbon were "the grid, the convergent square, the blocks and grid typologies as the reticulated grid translation by the authors" (Lamas, 1993, p. 224). The blocks were divided in plots that could have been used to build different kinds of buildings. The plots were sold mostly depending on its location in relation to the most important avenues. This organization method gave origin to a discontinuous development of buildings and of the plots occupation.

In contrast to what happened in the planning of *Baixa*, a block of Lisbon, the new avenues did not have an architectural development plan. The absence of restrictions in terms of construction gave origin to diverse kinds of buildings along the avenues. This fact is also referred by Silva (2006), as mentioned earlier, as she states that the poor architectural planning when compared with the great quality urban design planning, are one of the characteristics that one is still able to observe on today buildings present along the new avenues. In the late 1930s the expansion plan was not finished, as there were still some plots of land in the *Avenida da República* free to build on. However, there were already some building demolitions registered.

Analysis of Lisbon's subway network: 1959 – 2012

The development of a subway infrastructure plays a revolutionary role in the growth of a city. On one hand the subway follows the development of the urban fabric, on the other, it acts as the driver for the renewal of the latter.

In this case study it was shown that the subway was the main factor by which the *Avenida da República* saw major changes, mainly in terms of its buildings.

The first initial subway line of 1958 foresees a great city development encompassing the urban fabric of the new avenues through an axis starting in *Marquês de Pombal* and bearing *Entrecampos*.

Since 1959, the subway network has gained complexity being composed by four lines, 55 underground stations for a total of 43km. Of these 55 stations only 49 represent a "place" in the city of Lisbon (the remaining 6 stations are the result of the unfolding of existing stations due to crossings of two subway lines). Figure 1 shows that the majority of the expansion of the subway occurred in 1998 and 2004 as consequence of two major international events (World Exhibition – Expo 98 and the European Championship of Football in 2004).

As a consequence of the expansion of the subway networks, existing stations reflect that expansion in terms of the traffic to and through them. Considering the subway network as a graph composed of nodes (stations) and edges (connections) one can study the *betweenness* and the *closeness* of every station in this graph (Rodrigues and Sampaio, 2009). *Closeness* gives

the level of proximity a certain node is from all others, while the betweenness represents the role as intermediate in traffic between other stations.

Figure 1. Expansion of the subway occurred in 1959 and 2012.

Focusing on the stations that are directly situated in *Avenida da República* (*Entrecampos*, *Campo Grande* and *Saldanha*), all of which exist since the opening of the network, the role of the subway as driver of the renewal of the urban fabric was studied. In particular, it was important to show the subway changed the buildings in plots facing the avenue. To avoid boundary definition problems in the analysis this subset of the network was extended by one station in each direction of the 2012 network. In *Entrecampos*, *Cidade Universitária* was added and for *Saldanha*, *Picoas*,

S. Sebastião and *Alameda* were added.

In figure 2a) the betweenness of the seven stations shows that *Saldanha* always had an important role in terms of betweenness, but after 2009 this role has been greatly enhanced by the connections to *Alameda* and *S. Sebastião*. It means that this station is now the station that potentially can have more traffic going through it. It is an important point for the flow of people in the network.

Figure 2b) shows rank of the seven stations in terms of *closeness*. It is observed that once again *Saldanha* is in first position with the highest *closeness*. This means that it is also the station that on average will be closest to any other station making this station the most central station in the network. It is observed in this situation that *Picoas* also is highly ranked (4th place) in terms of *closeness* and that it had in the past higher ranking than *Saldanha* (mainly because it was connected to what was for many years the most central station, *Rotunda* (Rodrigues and Sampayo, 2009)).

Figures 2c) and 2d) show the evolution of the values of betweenness and closeness for the top 10 stations in the entire network ordered by the 2012 values. It is clear that in 2012 *Alameda* becomes almost as important in terms of *betweenness* as *Saldanha* and stations connecting to

Alameda like *Chelas*, *Olaias*, or *Bela-Vista* can now enter the top 10 in what was until now considered a peripheral area of the city. In terms of the stations of the new avenues we see that neither *Campo Pequeno* or *Entrecampos* make it into the top 10 in terms of *betweenness*, but *Campo Pequeno* ranks high (4th in 49 stations) in terms of *closeness* taking advantage of being just one connection away from *Saldanha*. *Saldanha* has become the new central station of the city after many years where *Rotunda* occupied first place.

In summary both *betweenness* and *closeness* show that the centrality of the subway network stations is shifting towards the stations of the new avenues, namely *Saldanha* and *Campo Pequeno* are becoming the new centralities of the network.

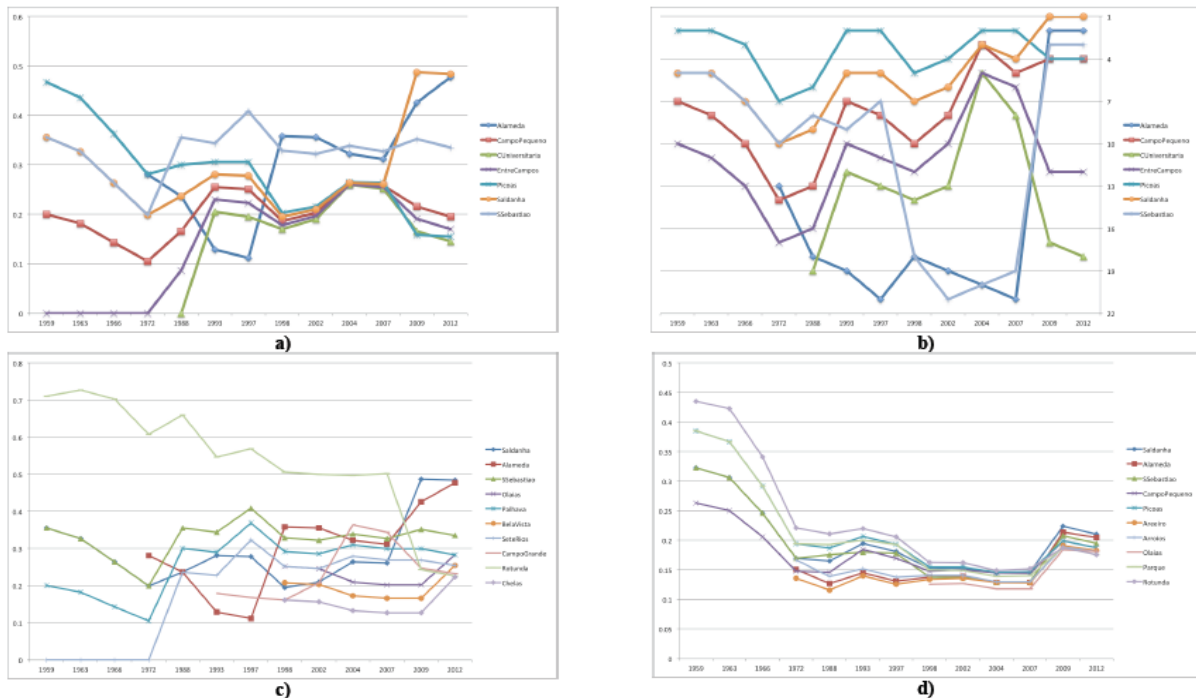

Figure 2 a) Betweenness of the 7 stations serving the new avenues; b) rank of the 7 stations serving the new avenues in terms of Closeness; 3) Betweenness evolution of the 2012 top 10 stations at different phases of the subway expansion; 4) Closeness evolution of the 2012 top 10 stations at different phases of the subway expansion.

Graphical Analysis of the 1908, 1950, 1970 and 2014 Cartography

The graphical analysis is based on the study of the different cartography found for the years of 1908, 1950, 1970 and 2014. Several synthesis drawings were generated using ARCGIS that facilitate the reading of the several timeframes of this boulevard.

This study presents a detailed analysis of the buildings in *Avenida da República* taking into account their evolution over time. The original plan for this boulevard was made in 1889, making the time frame for this span between 1889 and 2014. The buildings are characterized by the construction dates, demolition date, by the architects that designed them, by the number of storeys of the different construction phases, and by the different functions that they had over time. This research includes all the existing buildings and pre-existing buildings of *Avenida da República*, and also the buildings of the square Duque de Saldanha and the buildings of the roundabout of Entrecampos.

Concepts

To be able to synthesise the outcomes of this research, it is necessary to explain here some concepts usually used in the context of urban form studies and that are applied in this work in the context of the study.

This research has considered the following concepts:

‘Public Space’ – this is a space not built. The public space can be subdivided in two types: i) the linear public space, corresponding to channels of movement like streets, avenues and ii) the non-linear public space, corresponding to the places of staying like squares and ‘largos’ (Sampayo, 2011:69). In summary the public space is made of all the circulation space and the permanence space in the urban form. It is always made with the aim of solving questions related to the urban design.

‘City block’ – It is an element that can generate and be generated by the urban fabric. The city block has the particular characteristic of being a regularity, a structure, in the urban layout. It is in this way important in “the local concretisation of a certain model of city, in the conception of ways of life, in the shaping of the space and the architecture that builds the city...” (Coelho, 2013, p. 123, translation by the authors).

‘Avenue’ – It is an important public space of the urban agglomerate. It integrates the two types of public space: the linear public space and the non-linear public space. An avenue is usually designed in a very linear way and with great width, integrating both circulation and permanence spaces. Usually they are closed by the buildings that define it and by green spaces. The avenues gain particular importance in the urban fabric because of their ability to integrate buildings of major importance (commercial, monumental or cultural) usually at their endings.

‘Plot’ – It is a space of land “representing a land-use unit defined by boundaries on the ground” (Conzen, 1969, p. 128), usually with a regular shape (square, rectangle or other), that when associated with other plots defines a zoning area (Merlin and Choay, 2010, p. 448). The plot existence doesn’t imply its occupation by buildings in all its area.

Phases of the Evolution of the Urban Fabric of the New Avenues

The graphic timeline in (Figure 3) illustrates the evolution of the urban tissue in the new avenues and the integration of new grids adjacent to the initial plan. Only the streets that gave origin to the blocks were sketched. The original surroundings on the central area of the plan were not considered.

Figure 3. Urban fabric development of the new avenues around Avenida da República.

In 1908, the avenues grid was not fully defined yet. Important avenues such as the *Avenida de Berna*, the *Avenida das Forças Armadas* and the *Avenida Duque de Ávila* were on an early stage of development not creating significant hierarchies on the grid. On the borders of the plan the

grid is defined by considering the existent road network, which causes the appearance of blocks with different shapes.

In the plan of 1950, the project of the new avenues was finally concluded. Adjacent to the initial plan emerge new grids that highlight other influent avenues as the *Avenida Duque de Ávila* and the *Avenida Miguel Bombarda*. It can also be observed the extension of the *Avenida Praia da Vitória* Boulevard adjacent to the square *Duque de Saldanha*.

In 1970, the evolution of the grid does not present significant changes. Nevertheless, it is worth mentioning the introduction of new roads near the *Feira Popular*.

Finally, in the scheme of 2014 the grid is completed and consolidated. The most influent avenues as the *Avenida de Berna*, the *Avenida de Duque Ávila*, the *Avenida Miguel Bombarda*, the *Avenida das Forças Armadas* and the *Avenida da República* no longer present the sidewalk as a central band.

The blocks

The analysis of the growth of the different city blocks (Figure 4), can be made by comparing the following periods: 1908, 1950, 1970 and 2014. It was observed that the blocks had a slow evolution. In 1970, the most part of the blocks was still not completely defined.

Figure 4. City block evolution in Avenida da República.

In the 1908 chart, it is noted that the building development in the *Avenida da República* begins south close to the square *Duque de Saldanha*. The building development at north near *Campo Pequeno* and near *Mercado do Gado* can be considered as residual.

In 1908, south of the *Avenida da República* some blocks were already completed. Those blocks also define the first great perpendicular boulevard named *Avenida Duque d'Ávila*.

When comparing the charts of 1908 and 1950 it is observed that in the latter the blocks were almost completed. In the front blocks to the *Avenida da República* there were no plots left to build on. Nonetheless in 1950, it is still possible to find some free plots in the secondary avenues adjacent to the *Avenida da República*.

In 1970, the blocks undergo some modifications with the appearance of new empty spots. The demolition occurred mostly on blocks frontal to the *Avenida da República* and not so much in the secondary avenues as visible in the 1950 chart.

In 2014, it is observed that the blocks were finally consolidated as there no more free plots to build on. It is also possible to observe that construction grows out to the block interior, thereby occupying the remaining large empty spots.

The Buildings

As previously mentioned, the plan is developed from South towards North. This growth direction is clear by taking into account the density of existing buildings in the southern part of the area during the initial years of the avenue (Figure 5). In any case, the small number of buildings in the avenue in 1908 is not totally relevant for the future layout of the city. The 1908 plan already shows the city blocks adjacent to the avenue, allowing an understanding both in terms of its length and its width.

Figure 5. Evolution of buildings in the plots of Avenida da República.

The buildings of this phase are sparse and only in rare cases one observes plots being merged into a single construction. Buildings present diversified architectural characteristics namely the varied depths of construction into the plot and the varied sizes of the frontages.

In the plans of 1930 the buildings are not so far apart. The limits of *Avenida da República* are finally established. In this period all the plot sides facing the avenue are now built. Each city block pacing the avenue has between 3 and 13 plots facing the avenue, but the majority of them show an average 5 or 6 plots. In the 1950s it is observed that all the construction is made without voids between consecutive plots.

By the 1970s some of the constructions start to disappear and some plots facing the avenue become empty again. Some of these plots are merged with others and in some cases the total size of the frontages and the plot depth are extended.

In the present all the plots facing the avenue are built and one can observe that cases where plot merging and subsequent increase of frontages happened.

City blocks have now between 1 and 10 plots and the majority of the city blocks now present 4 or 5 built plots.

Comparing the map of the avenue (found in the archive of Arco do Cego), from 1902, with

the survey made by Silva Pinto (map of 1908), in terms of the number of plots sold, one can conclude that in 1902 there was a regularity in the drawing of the plots that is not observed in 1908. In the 1902 map the plots facing the avenue in the middle of the city blocks had identical dimensions while the corner ones were bigger. It is natural that some owners bought more than one plot and by 1908 the map shows a variety in term of the sizes of built frontages.

Building Height

When analysing the photos of buildings of that time one observes that those buildings presented no more than 5 or 6 floors. Nowadays, the buildings present in general more than 10 floors. From the 1950s until the 1970s, the number of floors increases significantly from 8 to 20 floors.

The schemes presented correspond only to the year of 2014 (Figure 6). The first one illustrates the buildings with 1 to 5 floors and identifies the buildings of the first phase of development of the *Avenida da República* from 1880 to 1920. The second scheme illustrates the buildings with 6 to 8 floors (from 1930 to 1950) and the third scheme illustrates the buildings with 9 to 20 floors (from 1970 to 2014). Finally, the forth scheme sums up the previous ones.

Today the most part of buildings with 10 to 20 floors are located on the block corners along the boulevard.

It is worth mentioning that the buildings nearer the subway stations are generally the buildings from the period between 1889 and 1950.

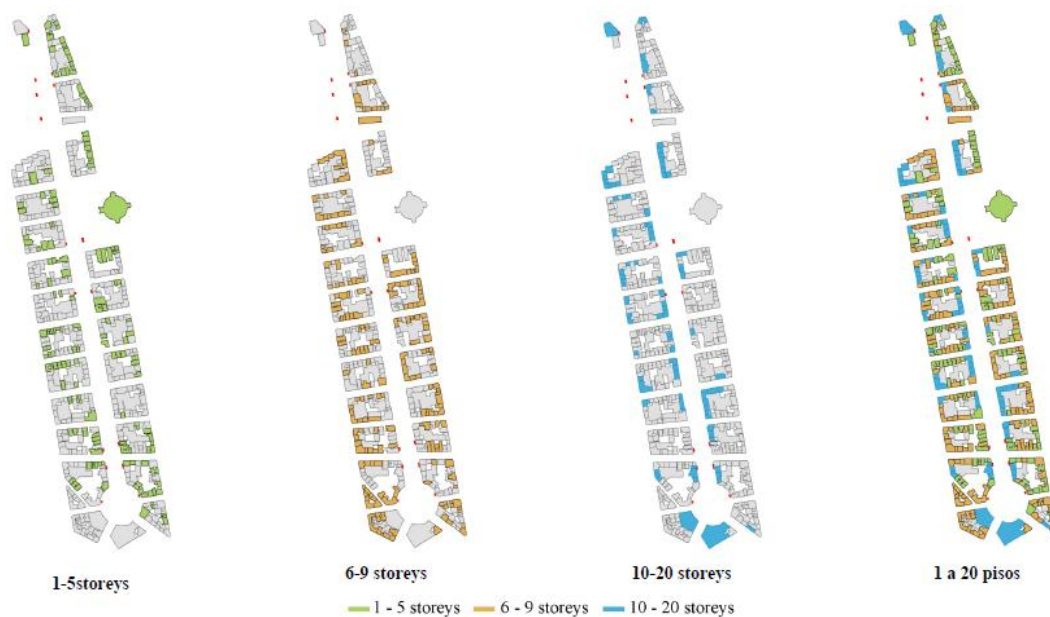

Figure 6. Number of storeys of the buildings in the city blocks adjacent to Avenida da República in 2014.

Function of the Building

Initially the most part of buildings of the *Avenida da República* were residential buildings. The buildings for business function were only introduced at the late 1950s. Figure 7 illustrates the function of the buildings as it is today.

Nowadays residence and business buildings occupy the front of buildings to the *Avenida da República*. On block corners near subway stations and bus stops it is possible to find mostly business buildings whereas on the central part of block fronts are present both business and residential buildings.

At the square *Duque de Saldanha* is where the buildings present the highest number of floors (Figure 6). Those buildings are mainly occupied by the third sector activities due to the eased access to public transportation systems.

Figure 7. Present function of buildings in the city block adjacent to Avenida da República.

Building Preservation State

The building preservation state, when considering the façade, was divided into 6 different classifications: i) 'Well preserved' – new building or not presenting any kind of anomalies; ii) 'Preserved' – building with some anomalies due to lack of maintenance; iii) 'Degraded' – building with severe anomalies; iv) 'Highly degraded' – Vacant buildings (inhabited); v) 'In construction' – Building in construction from the scratch; v) 'In restoration' – Building in restoration.

From the data collected in the beginning of 2014, 38 buildings were classified as 'well preserved', 60 buildings as 'preserved', 7 buildings as 'degraded', 4 buildings as 'in construction' and 3 as 'highly degraded' (Figure 8).

The buildings in better state of preservation are generally located on block corners. The buildings classified as 'preserved' are located mostly on the central part of block fronts. The

‘degraded’ and ‘highly degraded’ buildings are still from the early beginnings of the *Avenida da República* development.

Figure 8. Present condition of the buildings facing Avenida da República

Urban Void and Green Structures

In addition to the building evolution study, it is important to mention the green spaces role on the urban design transformation through the time. Ressano Garcia's plans goal was to integrate new hygienization solutions on the new boulevards. One of those solutions was the introduction of new green structures. When analysing the existent cartography from 1908, 1950, 1970 and 2014 it is visible the progressive disappearing of green zones on the *Avenida da República* (Figure 9). When observing to old photos it is visible that the subway integration gave origin to the removal of several trees.

Furthermore, the significant increase of traffic in this area forced the introduction of additional number of lanes. The need for a better traffic flow induces a reduction on the size of sidewalks, which used to contain the most part of planted trees.

Figure 9. Overview of green space development in Avenida da República.

Conclusions

It has been shown that the new avenues organised the structure of the public space, but didn't regulate the height of the buildings, neither did they regulate the architectonic typologies that define those spaces. The city is organised by a structure based on designed voids that need to be analysed and thought off in a chronological manner. The law of permanence of the plan attests the importance of the public space structure (squares, streets) as they resist the change of time. It is clear that the plan of the new avenues allows for the introduction of new rules over time that will improve its composition. Those new rules will weight in the typologies, the facades and the heights of buildings.

Ressano Garcia incorporated Haussmann social and urban sanitation and hygienisation ideas in the plan, but war more respectful of the existing urban features. He opted to keep and linearize many of the existing roads (some resulting from stigmergic foot paths), and chose to consider the particularly heterogeneous topography of Lisbon. With this balance this plan can is considered as a good illustration of urban design.

The subway and the stations built in Avenida da República (Entrecampos, Campo Pequeno e Saldanha) have a big role in the renewal of the buildings of the avenue. Saldanha always presented a high betweenness but has since 2009 become the most important station in terms of betweenness with the connections to Alameda and S. Sebastião. Together with having the highest closeness value, Saldanha is now the most central station in Lisbon with the most potential to see traffic being sent through and to/from its station. The placement of bus stops on the surface also potentiates further its centrality, making this station and its above ground square the new central area of the city. The analysis of the buildings in this square showed only buildings in normal and good conservation states. Nearby Saldanha station it is clear that a greater renewal and construction effort was made. This is in part justified by the role attained by the subway station over time being the most central station in Lisbon (just followed by Alameda).

In Avenida da Liberdade it was observed that Campo Pequeno is also becoming one of the most central stations of the network with positive effects on the renewal of the nearby plots. Near the Entrecampos station no particular changes were observed in the buildings in the past few years. This is in accordance with the lower values obtained for the centrality measures of the subway network.

This work also verified the law of the permanence of the public space through a reading of the cartographic material form 1908, 1950, 1970 and 2014 for Avenida da República and it was shown how the evolution of the buildings in the avenue are consequence of the expansion of the Lisbon's subway network.

Acknowledgments

The authors are thankful to Dr. David M. S. Rodrigues of The Open University, United Kingdom, for his mathematical insights and discussion on the subway network expansion measures. The authors are thankful to the students of architecture Sara Albuquerque e Pedro Baptista from the Lisbon University Institute, Portugal, co-authors of Carina Silvestre in the production of images 3, 4 and 7 for allowing their publication in this paper. The authors are also thankful to Mr. João Salmim Ferreira for his help with the translation of the document.

Urban chronicles: exploring the evolution of the entrepreneurial disposition of Coimbra's periphery

Ana Margarida Tavares

Department of Architecture, Faculty of Sciences and Technology, University of Coimbra. Ladeira da Santiva n.º153, 3030-029 Coimbra, Portugal.

E-mail: anamargaridatavares@icloud.com.

Abstract. *This paper is intended to assess if the roadway infra-structuration of the peripheral areas of the Coimbra municipality (Portugal) plays a significant role as an engine of urban reorganization and territorial cohesion in the perspective of the long-term evolution of municipality's morphology and land use. To achieve this aim we examine the eastern parishes of Coimbra, long known for their industrial and entrepreneurial character, though the delineation of a longitudinal dataset on the human appropriation of their territory. The methodology entails the construction of chronological series of axial maps of the area, which are associated with satellite images from the Global Land Survey Landsat and data collected from the Portuguese national registration of corporate entities. The combined analysis of these informations permitted to identify the morphological parameters of change and continuity that are responsible for the maintenance of the economic strength of these parishes throughout the years, and to summarize the reasons for their success inside Coimbra municipality.*

Key Words Coimbra periphery, roadway infra-structuration, economic strength, Space Syntax, Landsat

The ordinary way of life

Ordinary, banal or mundane are words that are rarely used in the architectural academic field to describe something that is worth studying. Nonetheless, ordinary, banal and mundane may well be the words that best convey the reality of both the western contemporary architecture and the western contemporary urban development system.

Described as “emphatically un-monumental, anti-heroic, and unconcerned with formal extravagance” (Harris, 1997), these everyday architectural pieces and their surrounding urban spaces are much more devoted to serve people's necessities on every aspect of human life as it is routinely lived, than to fulfill people's desires for a certain aesthetic pattern in their lives.

In his 1987 essay “The Everyday and Everydayness”, Henry Lefebvre argues that the notion of “everyday” is a product of the contemporary world, “the most general of products in an era where production engenders consumption, and where consumption is manipulated by producers” (1987: 9). Therefore, “everyday” is “the most universal and the most unique condition, the most social and the most individuated”, but also “the most obvious and the best hidden” of our time.

In fact, the never ending repetition of gestures of human life, whether commuting, working, consuming, or having leisure time, is itself most of the times taken for granted, somewhat like as it was as natural as the cycles of nature, such as day and night, hunger and satisfaction, activity and rest or life and death. Nonetheless, these ordinary everyday actions are in fact deeply related to the space where they take place; they are products of the human-constructed space that hosts them and permits their occurrence (Lefebvre, 1995). Plus, all such actions and human relations have in common a general law of functionalism, a stipulation of a certain range of functions, ordered according to the legibility of the forms and structures that serve them, creating this way, a system of mutual support.

This mode of spatialisation of the society is arranged in a system of different types of networks, both physical and intangible that occur at every moment, continuously, and infinitely. The type of network that this paper addresses is the mobility network of goods, people, energy

and information (Ascher, 1995), which creates various types of systems of interdependences and relations, both at global and local scales.

This network reality is described by Castells (1993) as a “space of flows” and is explained by Delalex (2006: 62-65) through its four main features:

1. It relies on the simultaneous coexistence of events and social interrelations more than on their contiguity in space. This spatial form of interaction is constructed from social relations that are detached from the physical contiguity and live in the space of flows;

2. It is supported by a series of global infrastructures used to carry both hard copy information (through transportation infrastructures like motorways, airports and mail) and electronic signs (through co-axial cables, fibre-optic cable or satellite) (Lash and Urry cited by Delalex, 2006: 63);

3. It is simultaneously concentrated and dispersed. Delalex explains that cities tend to develop as loosely interrelated exurban constellations that emphasize long distance interdependencies and minimize the role of territorial contiguity. On the other side, certain types of organizations, namely those related with economic activities, tend to concentrate in areas that have greatest access to advanced infrastructures of communication, at relatively affordable costs. The geography induced by the space of flows is therefore neither an effect of concentration, nor an effect of dispersion, but an intricate association between the two.

4. It's geometrically varied and the absolute geographical position of the objects is less important than their position within global networks. The geographical hierarchy is by no means definitive or stable, which implies a great flexibility and adaptability to the potential and requirements of the network of flows.

The following sections will explain how these assessments materialize in our case study.

The Coimbra municipality as a case study

Paraphrasing Lefebvre, the study of the banal isn't necessarily itself banal (1987: 9), since the ordinary that is present on the human life also encompasses the extraordinary that we can't (or ignore how to) appreciate. In this sense, both stressed citizens and unwary investigators may miss out the relevance of the everyday urban infrastructures, depreciating or devaluing their power in maintaining the contemporary pattern of urbanization, which this paper tries to tackle.

Hypothesis, aim and context

We believe that the characteristics of the mobility networks of goods, people, energy and information (Ascher, 1995) is relevant for the expansion and functional polarization process of new urbanized areas, pattern of urbanization of increasingly importance in contemporary occidental cities. We also believe that functional urban polarization is better understood if analysed through the forces that act on the actual processes of the territorial structuration.

In fact, the study here presented is part of a wider research that aims at discussing the role of high speed roadway networks as structuring elements of the new centrality systems located in the periphery of the traditional, compact urban centres. This way, we evinced (Tavares, 2013a) that roadway infra-structuration is an important mechanism of territorial cohesion at the periphery of the Coimbra municipality, in Portugal. We also tested the roadway infra-structuration attraction role for a diversified set of urban equipment that prioritizes the connection to the transportation networks of people and goods instead of the proximity to the consolidated urban core (Tavares, 2013b). The ensuing development of this line of investigation raises the question about how far the narratives of the observed integration and spatial connectivity of the roadway networks are in fact supported by a long-term perspective on historical evolution of the morphology of the Coimbra periphery and of its land use.

From this main proposition, the following questions arise: (i) Is it possible to reveal the morphological parameters that explain the settlement of industrial and entrepreneurial

equipment at the periphery of the Coimbra municipality? (ii) Is the pattern of urban organization and territorial cohesion around the roadway network presently observed also perceptible in the past? (iii) Is it possible to outline a chronological dataset of the industrial and entrepreneurial appropriation of these peripheral parishes?

Methodological procedures

In order to answer the questions outlined above, we opted to use a combined methodology of analysis, based on the confrontation and complementation of three different sources of information.

In order to reveal the morphological parameters of accessibility of these parishes we employed the Space Syntax methodology of analysis. In the first place, we collected the Coimbra's military cartography (sheets 229, 230, 240 and 241), which is available for the years 1947, 1984 and 2002. We chose to use exclusively the military cartography in order to guarantee the stability on the representation patterns of the territory, even if the time slot between the charts is not homogeneous. These charts were used to produce the correspondent axial maps of the municipality, from which the analysis of the Global and Local Integration and Choice variables were performed. The software used for this purpose was Alasdain Turner's Dephtmap.

We would like to stress that the scope of this study is restricted to the eastern parishes of Coimbra (São Martinho do Bispo, Ribeira de Frades, Taveiro, Ameal and Arzila). However, we decided to use the axial maps correspondent to the entire area of the municipality: an axial analysis performed partially could induce errors and reading misinterpretations due to the scale of the system itself, and also to the lack of representation of the connections with other major roadways, which we wanted to avoid.

Respecting the assessment of the parishes' pattern of territorial organization, we resorted to Esri's Change Matter website (<http://changematters.esri.com/compare>). This tool uses the US Geological Survey and NASA operated Global Land Survey Landsat data to display the Earth surface at six time epochs (1975, 1990, 2000, 2005 and 2010), in a combination of the visible and infrared portions of the light spectrum. In these infrared images vegetation appears red, water appears blue and human constructions appear grey (among other categories), which is very useful when it is necessary to detect changes, such as deforestation, fluctuations in water elevation or urban sprawl, on the landscape. For this study, the infrared images were used to uncover the modifications on urban density of the parishes.

For the study of the economic patterns of land appropriation, we used data provided by the *Registo Nacional de Pessoas Colectivas* (national registration of corporate entities, in a free translation), a section of the *Instituto dos Registos e Notariado* (the Portuguese institute of registry and notary). The collected information regarding all the corporate entities based on these parishes since the beginning of the registration (the oldest entry is from May 1930), and included, among other information, the date of their establishment, their address, the CAE (*Classificação Portuguesa de Actividades Económicas*, or Portuguese Classification of Economic Activities) and the date of their extinction. This information was processed in the form of several charts and analyzed in tandem with the axial maps.

In this respect, we should mention that the national registration of corporate entities only started to collect the "extinction date" data since 2009, reason why there are surely entities erroneously represented in some of the chronological maps. We are aware of that fact, but we believe that the advantages of using this information outweigh punctual inaccuracies that may exist in the representations.

Data analysis and interpretation

Global axial analysis

As said above, we performed the axial analysis of the whole of Coimbra municipality for the years 1947, 1984 and 2002 and the axial maps, when placed side by side, showed an ever changing territorial reality. Please note that the darkest lines on the images presented are equivalent to the red lines on the more classic red-blue colored axial representations, and are thus the most integrated ones. Also note that the lighter the lines become, the least integrated they are.

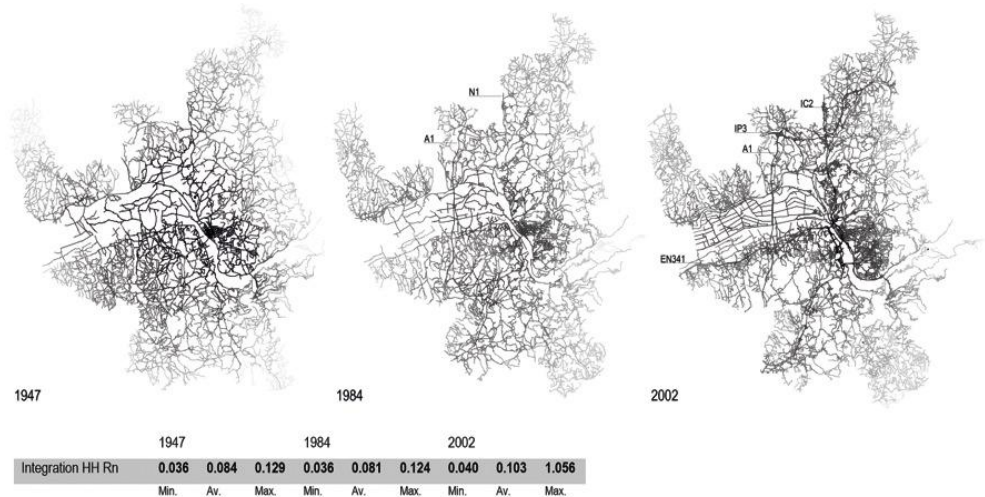

Figure 1. Global integration maps and numeric values for 1947, 1984 and 2002.

Analyzing the Global Integration maps (Integration HH) on Figure 1, it is clear that a process of urban consolidation has been taking part throughout the years. It starts with a fairly dispersed set of highly integrated routes, yet located on the central area of the 1947 map. The more elongated representation of the 1984 map follows, assuming the N1 (*Nacional 1*) and the recently inaugurated A1 highway (1982) as part of the ensemble of the most integrated roadways of the system. Finally, the 2002 map displays a more balanced urban network, encompassing a strongly connected center (that corresponds to Coimbra’s downtown, alongside the Mondego river) and strong roadway connections, represented by the N1 (that in the meantime experienced enhancements that transformed it into an expressway, now known as IC2), the Taveiro’s Expressway (the final part of the EN341, the national roadway that connects the coastal city of Figueira-da-Foz to Coimbra), the highway A1, and also the IP3 national roadway (that connects Coimbra to Viseu).

The numeric values corroborate the visual impression by displaying a drop on the average Global Integration values in the year of 1984, abrogated afterwards on the 2002 representation. This last map inclusively overtook the 1947 values, disclosing a strengthening of the global accessibility of the entire system.

Concerning the Local Integration Maps (Integration HH radius 5) on Figure 2, it is also perceived a drop on the average Local Integration values on the 1984 representation, compared with the 1974 situation. But, also in this case, both the average and maximum values of integration raise in the 2002 graphical and numerical data. In general terms, it is observable that the 1974 trend of having several well connected local agglomerates was partially lost in 1984, being replaced by a concentration on the Coimbra historic town and downtown, a similar outcome to what we observed for the Global Integration. The 1974 pattern is restored in 2002, with more peripheral agglomerates being better connected with the main roadway axis.

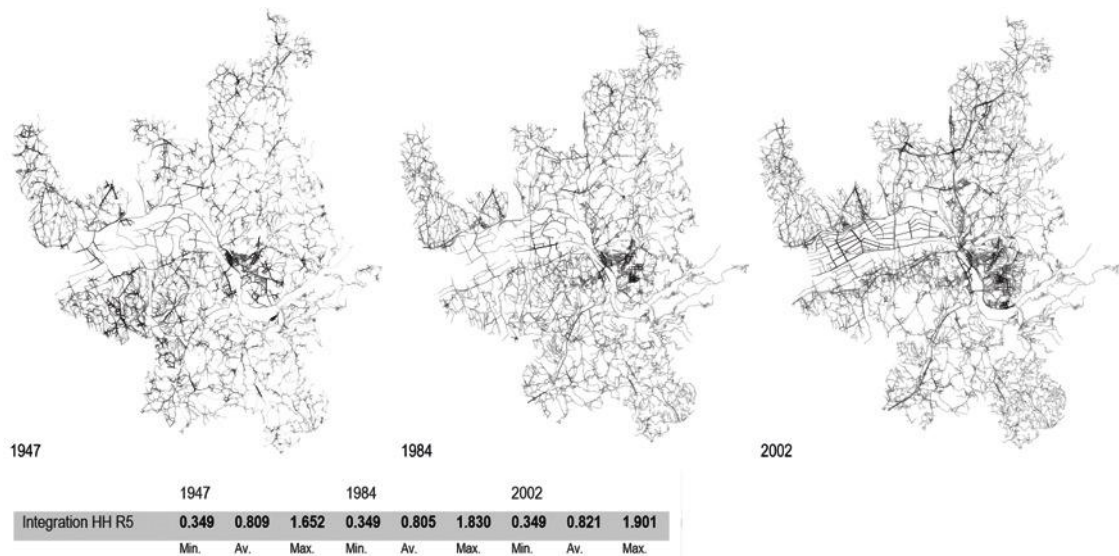

Figure 2. Local integration maps and numeric values for 1947, 1984 and 2002.

Figure 3. Choice maps and numeric values for 1947, 1984 and 2002.

The confirmation of these observations was made resorting to the Choice map and values on Figure 3. However in this case all values increase continuously over time, the correspondent axial maps reveal a change in the pattern of use of the Coimbra roadway system: in 1947 it appears to be fairly structured around a few main road axis, the ones most likely to be chosen from any given position of the system. In the next map, the polarization power of these few roadways seems to be minimized and the system appears to be more fragmented in general, as more roadways appear with darker colorations. The final map shows a return to the previous patterns of attraction, stabilizing into a representation where the main roadways A1, IC2, IP3, Taveiro's Expressway and also the EN17, also known as Estrada da Beira (that connects Coimbra to Celorico da Beira, through some important towns, such as Vila Nova de Poiares and Arganil) prevail.

To conclude the general reading of the tripartite axial analysis of the Coimbra municipality, we reckon that not only the construction of some major roadways, namely the A1 highway (it's Condeixa-Mealhada section was inaugurated in 1982) and the IP3 (inaugurated in 1995), but

also the improvement of others, particularly the IC2 and the N341/Taveiro's Expressway, had major consequences on the patterns of movement throughout the municipality and on the patterns of accessibility of certain areas. Along the years, both the new and the transformed roadways created a destabilization *momentum* that had the fragmentation of usages as a main consequence. In most recent years, with the stabilization of the roadway development and with the creation of better punctual connections with the urban agglomerates, the system regained its equilibrium, in a very similar pattern to the older one.

Morphological parameters of change

Bearing in mind the findings expressed above, we proceeded to the analysis of the eastern parishes of the municipality. We both assessed the influence the roadway networks have for the urban organization and territorial cohesion of these parishes and outlined a chronological dataset of their industrial and entrepreneurial appropriation. We zoomed the axial maps previously presented in order to have a better perception of the color gradation of their axial lines.

In the *Global axial analysis* section we identified the EN341/Taveiro's Expressway as one of the most integrated axis of this municipality's roadway system. This roadway was constructed after the publication of the 1985 *Plano Rodoviário Nacional* (the national road network plan), as a direct result of this document's recommendations for the Portuguese roadway infra-structure. On the article 11, section II of this Plan, it is stated that it should be set up a construction programme of alternative roadways to those that cross urban agglomerates (Ministério do Equipamento Social, 1985: 3208). This indeed happened in Coimbra, as the construction of the EN341 deviated traffic from the municipal roadway that served and crossed all the small agglomerates along the left bank of the *Mondego River*, freeing them from the burden and hazards of the heavy vehicle traffic.

Figure 4. Global integration maps of the eastern parishes of the municipality.

This change between the 1974 and 1984 plans and the 2002 plan is perceptible on the Global Integration axial maps of Figure 4. It is particularly remarkable how well the EN341/Taveiro's Expressway nodal connection with the A1 highway seems to work, fostering the integrator power of this ensemble inside the system.

Patterns of territorial organization

Having such an extended history of constant changes, between new constructions (the A1 in 1982 and EN341 in the late 1980's) and improvements (the transformation of the EN341 into an expressway to better connect the highway exit to the Coimbra city centre, after the turn of the century), changes on the pattern of urban organization should easily be spotted. The Figure 5 is a succession of three satellite images we accessed through Esri's Change Matter website (<http://changematters.esri.com/compare>). The main feature of these images is that they were obtained by the infrared cameras of the Global Land Survey Landsat, presenting in a clear way

the differences between various types of territorial occupation. All three images are the result of the superposition of two other images, from different dates, highlighting changes on vegetation (such as agriculture, forest or meadow) and water levels (rivers and lakes or wetland for instance).

Please note that as these images are presented in grayscale, the darker coloration corresponds to vegetation decrease and lighter coloration corresponds to vegetation increase. Grey colorations correspond to absence of modifications. Also note that the first image represent the superposition of the 1974 and 1990 images, that the second are of 1990's and 2000's, and that the third represents the 2000 and 2005 images. This way, even if the dates of satellite captures don't correspond to the military charts that we used for the axial analysis, we're still able to have a complete coverage of the territorial transformations for the time period that we are addressing in this paper.

The major change we notice on the 1975-1990 superposition is a large decrease on the acreage of the right bank of the Mondego River, an area usually named as *campos do Mondego* (Mondego fields). This area is characterized by its low elevation and marshy soil and is mainly used for growing rice. The activity of the growth of rice in this area comes from ancient times, but the drop that the image shows on its cultivation may be the best proof of the change on the life and work paradigms that the adhesion to the European Union in 1986 (named European Economic Community at that time) brought to the Portuguese citizens. Another explanation for this disinvestment on agriculture may come from the fact that the construction of both the A1 and the EN 341 brought another type of territorial dynamic, with the development of modern urban conditions at the existing agglomerates and the arrival of new inhabitants, which were not as interested in farming the fertile lands of the Mondego basin as having a more specialized and well-paid type of occupation.

The 1990-2000 image shows a more localized pattern of change, especially regarding the decrease of vegetation around the roadway axis in three main areas: along the old roadway that crosses the urban agglomerates; at the Ameal and Arzila parishes; and at the area of the *Parque Empresarial de Taveiro* (Taveiro Business Park) and *Mercado Abastecedor da Região de Coimbra* (supply market), both inaugurated in the early 1990's. In this case it is clear that the motivation for the change is the infra-structuration and urbanization of these areas, which is the reality that we expected to observe.

Again the 2000-2005 image shows punctual vegetation decrease and densification of the urban area, namely on the Taveiro area (the *Parque Mondego Retail Park* was inaugurated in 2002), one of the parishes that developed the most since the early 1990's. By contrast, it is also observable a considerable increase on the farming area on both margins of the river. This fact might strike the reader for a moment, but it seems to be a natural result of recent year's assistance and support on agriculture by the Government and by the European Union, as well as of a rediscovery and "trendification" of the Portuguese national products.

Bearing in mind the readings expressed above, we feel confident to assert that there is a close relation between the roadway infra-structuration at the eastern parishes of Coimbra municipality and their territorial organization. These infra-structures, as constantly evolving entities, are inclusively responsible for the different types of patterns of territorial organization observed on different time periods.

Industrial and entrepreneurial appropriation

We also wanted to know if the roadway network of the eastern parishes of Coimbra have any influence on the settlement pattern of industrial and entrepreneurial equipment, and if this settlement pattern has been changing throughout the history. For that, we located on the military charts all the companies that have their headquarters in these parishes and that are listed at the *Registo Nacional de Pessoas Colectivas*. We then compared the result with the three Local Integration maps.

In Figure 6 we can see that right on the 1947 map, and despite having only six enterprises registered at that time, it is already clear that there is, in fact, a bond between the most accessible axial lines and their location. The same pattern is visible on the 1987 and 2002 maps, with industries and enterprises joining the others that were already set in place. However, we also observed that when they choose to settle on different locations, they tend to choose the most integrated areas of the parishes.

Figure 5. Landsat images of the eastern parishes of the municipality.

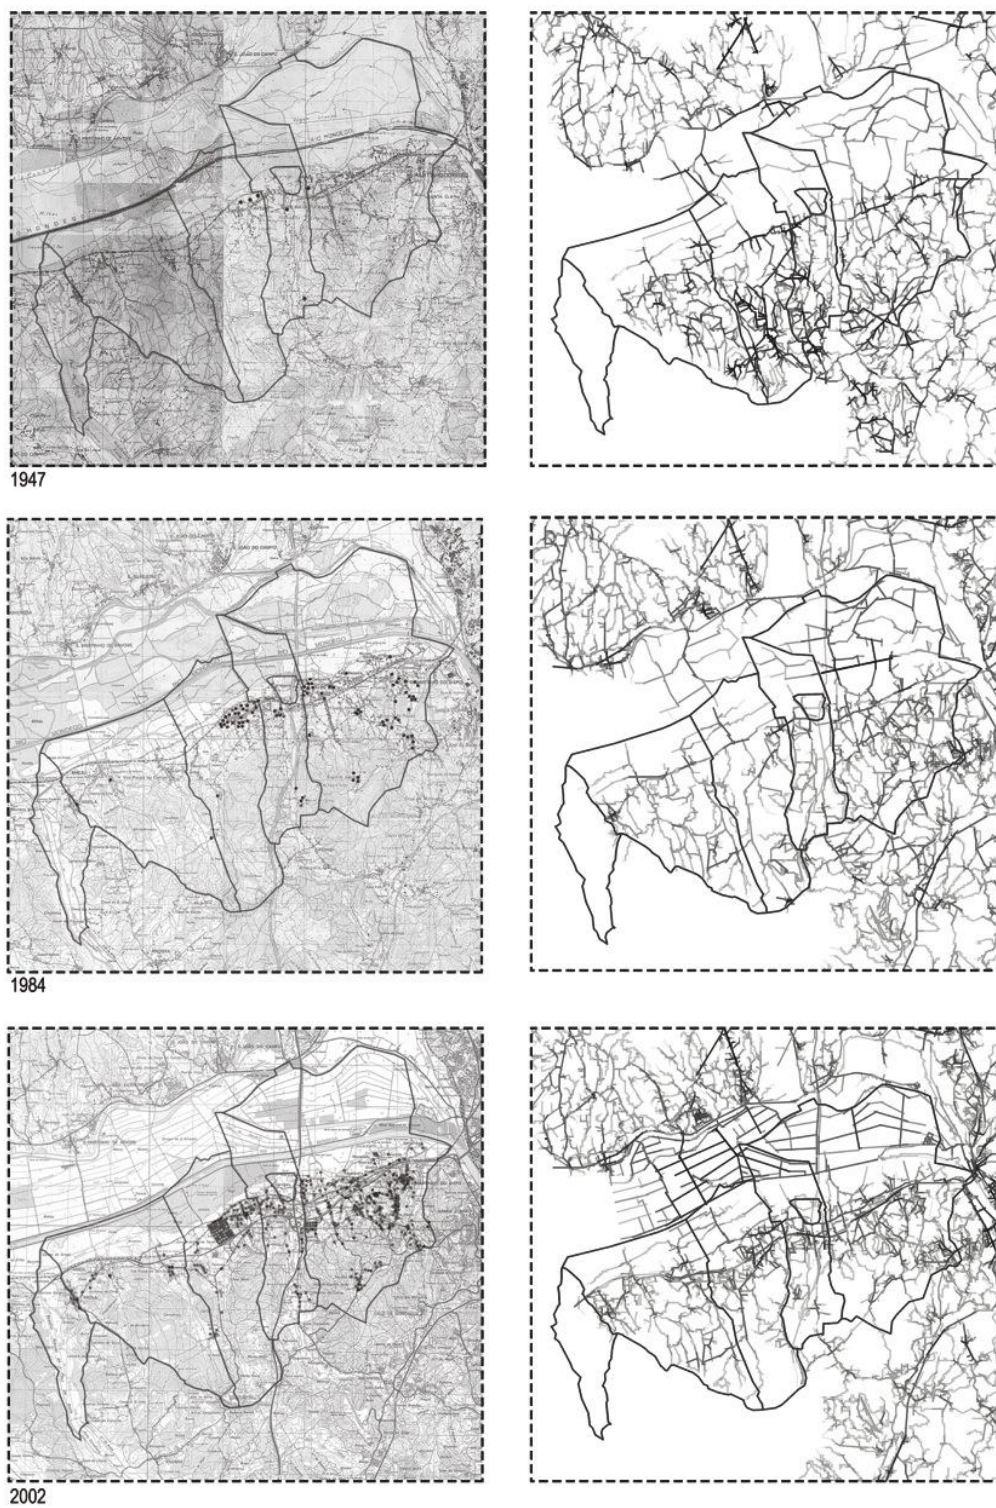

Figure 6. Location of the existing corporate entities for 1947, 1984 and 2002.

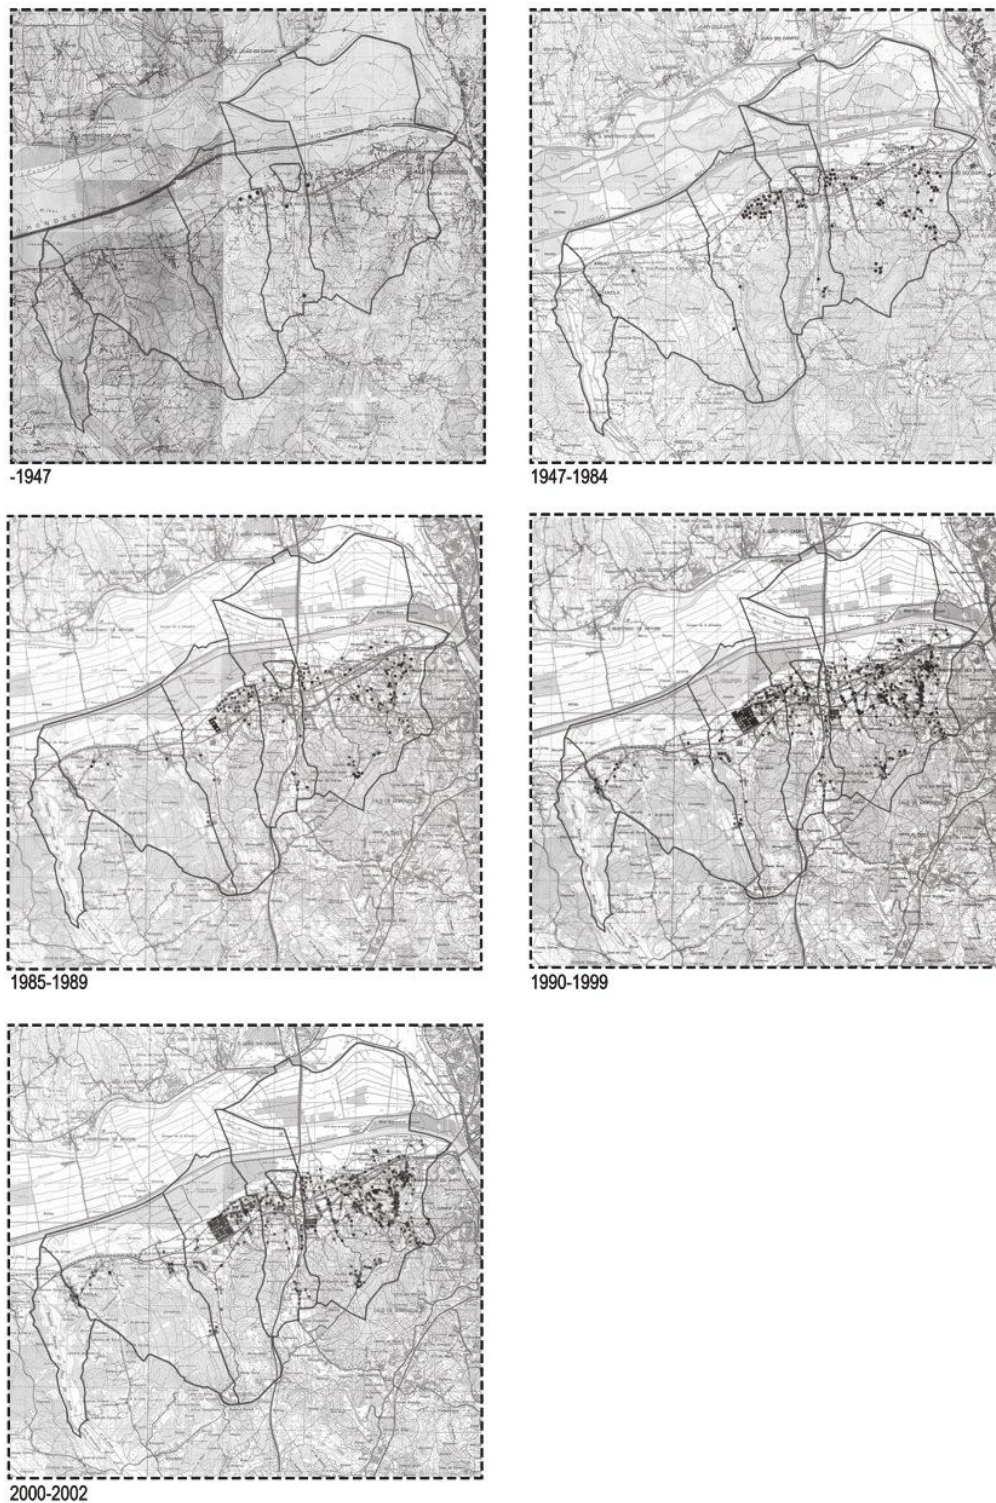

Figure 7. Location of the existing corporate entities for before 1947, 1947-1984, 1985-1989, 1990-1999 and 2000-2002 time periods.

Observing the settlement of these entities by different periods (before 1947, 1947-1984, 1985-1989, 1990-1999 and 2000-2002) in Figure 7, we can foretell the political and economic trends of each period. The 1947-1984 map shows the beginning of the industrial appropriation of the area, embodied in a slow start of the development process of a ruralized territory, located

just a few km outside Coimbra. In the 1985-1989 map we can see the installation of the first enterprise at the *Parque Empresarial de Taveiro*. From this point on, there are two different location patterns for the industries and enterprises along the Coimbra's eastern parishes: the first one is settling inside the business park, which have great advantages in terms of saving infra-structuration costs, dividing every-day operational costs and creating synergies with other enterprises; the other location pattern depends on each industry or enterprise assessment of the importance they give to factors such as accessibility, land cost, parking space, possibility of creating synergies, among other factor. This way, besides the consolidation of the business park, it is noticeable a preference on the agglomeration of enterprises in certain areas, and the choice for more integrated, hence accessible, areas. The 1990-1999's rends visible an "explosion" on the number of industries and enterprises, which is explained by the Portuguese adhesion to the European Economic Community in 1986 and the euphoric period that followed. With the financial support given by the EEC, specifically for the entrepreneurial development of the country, many had the chance to start their own businesses, and thus creating better life conditions for their families. Finally, the 2000-2002 map shows a stabilization on the process of opening new business activities. The establishment of the single currency in the EU brought new challenges to the Portuguese economy and the sense of euphoria suddenly dropped.

Nevertheless, the industrial and entrepreneurial presence inside these parishes is strong and visible until today. Of course the city continued to evolve after 2002, the most recent date addressed in this paper, but due to financial constraints and to the arrival at a point of equilibrium, the infra-structural changes haven't been as evident as in past times. This way, we dare to allege that the territorial organization hasn't changed much as well, maintaining the pattern that we described above.

Conclusion

At the beginning of this paper we claimed that we wanted to investigate how far the narratives of integration and spatial connectivity that are observed on the contemporary roadway infra-structures of the eastern parishes of the municipality of Coimbra are in fact supported by a long-term perspective on historical evolution of the morphology of these parishes and of their land uses.

We questioned if it was possible to reveal the morphological parameters that explain the settlement of industrial and entrepreneurial equipment at the eastern parishes of Coimbra, which we did through a set of three axial maps of the parishes, for the years 1947, 1984 and 2002. The analysis of these maps uncovered a process of urban consolidation that has been taking part throughout those years. We inclusively reckon that both the construction of some major roadways and the improvement of some others had major consequences on the movement patterns throughout the municipality, and on the patterns of accessibility of certain areas as well.

We wanted to know if the pattern of urban organization and territorial cohesion around the roadway network presently observed was also perceptible in the past. For that, we arranged a succession of three infrared satellite images that were the result of the superposition of two other images, from different dates. These images allowed us to understand the changes on land uses of the parishes, namely the increasing and decreasing trends of agriculture and urbanization. The results allowed us to assert that the roadway infra-structures, as constantly evolving entities, are responsible for the different types of patterns of territorial organization observed on different time periods.

We also wondered about the possibility of outlining a chronological dataset of the industrial and entrepreneurial appropriation of these parishes. For that, we used the data provided by the *Registo Nacional de Pessoas Colectivas*, which we located on the military charts and compared with the Local Integration maps. This comparison highlighted two different location patterns, being the first one the settling inside the business park, and the second one the dependence on the assessment of the importance of accessibility to each particular business plan.

Coimbra, as many other Portuguese cities, is constantly under constructive and destructive changes. The forces that create these changes are various in type and action and are not, by any means, banal or ordinary.

Abstract. *This paper explores the question of how built environment affects spatial cognition. It is focused on two 19th century Lisbon (Portugal) burial grounds (Alto São João and Prazeres). These cemeteries were founded at the same time, but in result of different urban-social and political concept gained different spatial expression. Using Space Syntax theory and Depthmap software, the paper approaches axial and visibility parameters, connectivity and integration, that are put into a cross comparison with real estate and burial service prices, aiming at identifying spatial similarities and differences, with a focus on social segregation expressed through the cemetery planning. Findings suggest the chess-like grid (common for both cemeteries) and the connection among parts are crucial for general spatial cognition's performance. Besides that, the cemetery "design", at a certain level, reproduces diachronically the urban ethos. A more refined intelligibility depends on the conceptual framework: community vs. lonely mourning.*

Key Words: Cemetery, Lisbon burial grounds, burial services, spatial analysis, Space Syntax

Introduction

Cemeteries of the 19th century Lisbon result from the urban ideas, that took them out of the city fabric together with asylums, slaughterhouses and prisons. The two cases of this study were the first burial grounds in Lisbon that responded the tendencies. However throughout 2 centuries they have developed in slightly different manners, though maintaining common social features in their morphological nucleus.

A burial system in Lisbon presents a list of different services of a cemetery and several burial options differing in price (Câmara Municipal de Lisboa, 2013: 14; 2014: 151), pushing the whole cemetery into a structure of social inequality. This social premise is examined morphologically in two cemetery plans. The root of both cemeteries is *cardo* and *decumannus*, where the center is the most sacred, crowned with a chapel and expensive, richly decorated private burials – *jazigos*, serving as the tourist attractions nowadays. Getting away from the sacred center, the "prices for death" go lower, and the burial ground gradually becomes more profane.

A further study of social stratification considers Space Syntax theory (Hillier, Hanson, 1984) applied to cemetery plans and retrieving the axial graphs from Depthmap software, focusing on 2 main variables: integration and visibility.

Integration "basically represents the amount of steps it takes to get from one particular location to any other in the environment" (Kalff, 2012: 10). Integration, following the formula described by Hillier and Hanson (1984: 108), considers a value for a mean depth and a number of axial lines in the system. Parts of a structure of the highest values of integration usually are found in the city centers (Holanda et al, 2012), same organization is found in Alto de São João cemetery.

An isovist, or viewshed, is the area in a spatial environment directly visible from a location within the space. (Turner et al, 2001, for details). This variable is important for its capability to show the variations of visibility pattern associated to different kinds of spatial conditions around different burials.

The study is complemented with some data from a questionnaire, carried by Egle Bazaraitė. The questionnaire focuses on the visitor's sense of orientation in burial grounds, the habits of the visitors and their expectations of spatial qualities of the cemeteries. Comparative table of different aspects of two Lisbon cemeteries concludes the paper.

Premises: notes on the history of urban cemeteries

The 18th century marks an important turning point in the cemetery culture in the Western world. At the time illuminist and hygienist ideas were applied to the cities, taking cemeteries, slaughterhouses, asylums and prisons out of the city (Ariés, 1976). These institutions, placed in the populated city territory, were seen as impure (Oliveira, 2007: 65).

Literary and art works appeared approaching the phenomenon of death, revisiting the idea of the paradise, the world of the antique deities, awaking the nostalgia of the past that served as a key image to the Romantic movement of the 18th century. Thomas Gray lingered in the poem "Elegy Written in a Country Churchyard", as well as many other English poets, that described cemetery as the place for meditation (Oliveira, 2007: 53). All these tendencies led to questioning the position of cemetery in the city's intramural structure, leading to constructing the tombs and sepulchers in the open natural context and starting to apply Ancient Egyptian and Classical Graeco-Roman burial models in different scales (Etlin, 1991: 178; Curl, 2002: 189-196). Simultaneously, doctors, city planners and scientists focused the attention to the salubrity of the overcrowded cemeteries/charniers, located inside the cities and in the church territory.

These ideas gave an impulse for the great changes in cemetery culture. Garden cemetery appeared as a new, but in fact revisited alternative to the cemeteries. Various parks have been created in England (Stowe Garden, Leasowes, Howard castle *inter alia*) and in France (Ermenonville, Mauperthuis, Monceau *inter alia*), receiving mausoleums and tombs, sometimes fake, though evoking the nostalgia for the wisdom of the ancestors. "Now the cemetery was to be a picturesque landscape garden which conveyed a radically different understanding of death" (Etlin, 1984: 146).

Cemeteries were to include new aesthetical functions like "*embellishment* of the city" (Etlin, 1984: 41), as well as a moral message by honouring "worth of ordinary citizens" (Etlin, 1984: 42) serving "as a school of virtue" (Etlin, 1984: 59).

Père Lachaise was established in the existent gardens and constituted "the final stage in the ongoing debate about how social values and sentiment should be accommodated in the new Arcadian landscapes for the dead" (Etlin, 1984: 229). The types of burials have been defined, dedicated to different classes according to their financial capacities.

French approach to the burial gave an impulse to the creation of similar cemeteries around the Western world. Different urban contexts and natural conditions of climate helped those burial grounds with the same root of ideas and architectural expression evolve into the structures with local characteristics.

Burial system in Lisbon cemeteries

Taking into account the premises, the analysis conducted in this paper is based on the syntactic investigation of the two oldest existing Lisbon cemeteries: Prazeres and Alto de São João. All in all there are 8 cemeteries inside the city of Lisbon (figure 1) and the burial system and taxes are regulated by City Townhall (Câmara Municipal de Lisboa, 2013: 14; 2014: 151).

Figure 1. Axial map of Lisbon: the darkest black lines show the potencial urban core. 5 main burials grounds and 3 smaller supplementary ones are located outside the urban center.

Different options of burial imply different expenses. Presently there are 7 options: temporary sepulcher, perpetual sepulcher, ash field, private burial construction – charnel house (*jazigo*), public burial construction – charnel house (*jazigo*), public ossuary, private or public columbarium.

The options can be divided into two groups: one can either use a family *jazigo* for burial (private *jazigo* or perpetual sepulcher) or the options of public equipment. Both choices imply service fees, however in private burial the fee of a burial service is paid once, while for burial in public constructions it is paid for a certain period of time (1, 5 or 25 years). When this period is over, a person responsible for a buried body has to pay the fee again. If there is no one to take care of the situation, cemetery rules define “taking care of the bodies in the most appropriate way to the situation” (Câmara Municipal de Lisboa, 2013: 10). Table 1 presents values for burying in Lisbon cemeteries. The values are different from one city to another since they are defined by the local authorities.

For burial in a private *jazigo* or perpetual grave, a piece of land must be acquired from the municipality, and the construction costs are to be paid by the acquiring person (Câmara Municipal de Lisboa, 2013: 14; 2014: 151). This person decides on the architectural style and materials of the project, though following the regulations defined by the municipality (Câmara Municipal de Lisboa, 2013: 14) (table 2).

This data must be seen in the context of the minimum wage in Portugal for 2014, that is 565,83 euros (Fundação Francisco Manuel dos Santos, 2014). 1 m² for private *jazigo* is almost 3 minimum wages, and perpetual grave costs more than 17 minimum wages.

As a burial ground is a paid service, it makes sense that people acquire services responding to their financial capacities, and though interested in decent treatment of the passed away, rare one would go over his/her financial limits or even into debt for paying the funeral.

Table 1. Fees for burial in public cemeteries in Lisbon, 2014 (Câmara Municipal de Lisboa, 2014: 151)

Type Of Burial	Period	Fee In Eur (2014)
Burial in Temporal Grave	once	85
Burial in Perpetual Grave	once	145,65
Burial in Ash Field	once	52
Burial in a Private <i>Jazigo</i> (Charnel House)	once	189,55
Burial in a Public <i>Jazigo</i> (Charnel House)	1 year	116,8
Burial in a Public <i>Jazigo</i> (Charnel House)	5 years	306,15
Burial in a Public <i>Jazigo</i> (Charnel House)	25 years	1712,6
Burial in a Public Ossuary	1 year	98,1
Burial in a Public Ossuary	5 years	201,65
Burial in a Public Ossuary	25 years	615,1
Burial in a Public or Private Columbarium	1 year	95,45
Burial in a Public or Private Columbarium	5 years	188,45
Burial in a Public or Private Columbarium	25 years	562,1

Table 2. Prices for land concession in Lisbon cemeteries (Câmara Municipal de Lisboa, 2013: 14)

Concession Of Land For:	Price For:	Price In €
private <i>jazigo</i>	1 m ²	1619,7
perpetual grave	1 lot	9718,1

The ones unable to pay burial service have a financial support from the religious charity institutions, eventually covering the expenses for the most appropriate (supposedly the cheapest) way of burial.

Burying in Prazeres burial ground is not possible anymore, unless a deceased belongs to the family that owns a private *jazigo* or a perpetual grave. This burial ground is in a kind of state of conservation, turning itself into a pure museologic jewel of Lisbon tourist map with various guided visits.

In the case of Prazeres cemetery, one can only purchase a *jazigo* from another family, which would “abandon” it by taking away the coffins, and sell *jazigo* in an auction. As newspaper (Alemão, 2013) announces, the price of *jazigo* in Prazeres cemetery can go up to 150.000 euros. Alto de São João cemetery today is the most central burial ground in Lisbon, that includes crematorium and gives service of all possible burial options defined by law.

History of Prazeres and Alto De São João cemeteries

During the 19th century the nucleus of the current Lisbon cemeteries have been founded (except Carnide), and even after various transformations their initial structure is still present.

Both – Alto de São João and Prazeres cemeteries – were founded in the first half of the 19th century – precisely in 1833 during the cholera epidemic for handling the great number of victims. The cemeteries were placed in the outer parts of the city territory, both occupying

beautiful undulating topography with the views to Tejo. Burial grounds were established in peripheral and rural suburbs of Lisbon, that in the middle of the 19th century still served agricultural purposes (Oliveira, 2007: 252).

Alto de São João was planned in the Eastern part of the city, occupying existing São João estate. Prazeres cemetery was founded in the Western part. These cemeteries, established at the same period received quite different “inhabitants”. Prazeres served for the burial of liberal figures – politicians and writers of the period, including the nobles and the enriched bourgeois. Alto de São João cemetery obtained political mission, though of a later period, serving the masonry and institutional monuments erected by the initiative of *Estado Novo* (Oliveira, 2007: 254).

The idea of preserving the memory, and burial ground as a place for education and evocation of moral, including value of historical conscience, turned this space into some kind of the museum. Several project proposals have been made for the Alto de São João and Prazeres burial grounds. Nowadays the responsibility of cemetery planning belongs technicians (including architects) working in municipality.

The site chosen for development of Prazeres cemetery had been used for burials in the periods of epidemic crises since the 16th century. The site included as well an existent chapel. Prazeres grew twice its size; while Alto de São João has grown by 3 times since it was founded.

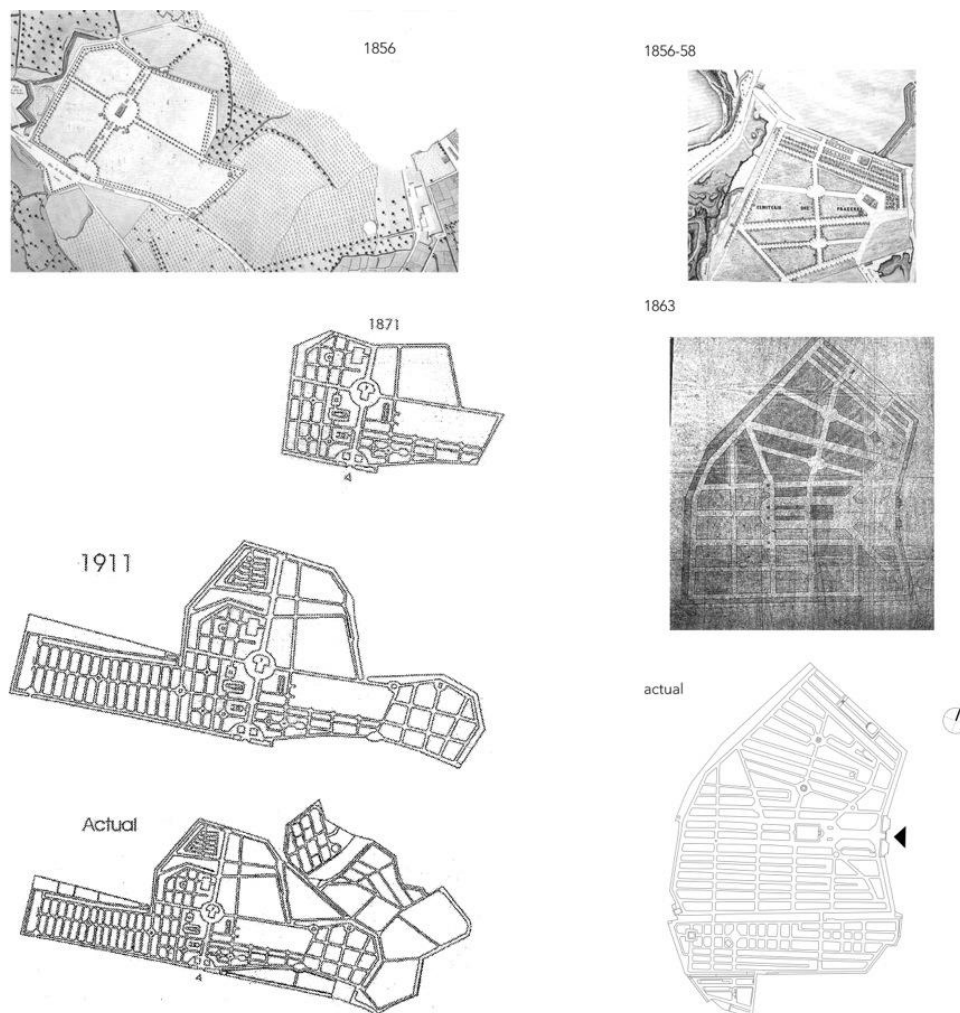

Figure 2. The development of Alto de São João and Prazeres cemeteries (Oliveira, 2007: CCLVI, CCLXII, Ferreira, 2009: 1139).

Comparison of the urban context of these two cemeteries

Prazeres cemetery is 1.5 km away from the nearest metro station (Rato), and it takes about 21 min to get from one point to another⁴³. (Buses of 5 different routes (712, 701, 709, 774) and trams of 2 different routes (25, 28) take one almost to the gate of the cemetery.

Alto de São João burial ground is 1.2 km away from the nearest metro station (Arroios), and it takes about 17 min to make the distance on foot. Buses of 2 different routes (718, 742) stop at the gate, and buses of 7 different routes stop 600 m away from the entrance (at Paiva Couceiro square: 206, 706, 718, 730, 735, 742, 797).

There is certain group of people that are interested in burial grounds as public places, using them as a kind of parks with historical contents. The same approach in the 19th century revealed the necessity of a public park - a kind of a public space that did not exist before (Etlin, 1984: 367).

38 respondents age 20-68 filled in the questionnaire prepared by the author of this paper. Though it is still early to make the conclusions, it is interesting to note that those burial ground visitors interested in a burial ground as a place for a walk – public place, might not have any sentimental connection to the graves of their family members and would have a difficulty to explain where exactly these graves are in the certain burial ground plan. Respondents that mentioned this had university education and in most cases were connected to arts. They would visit a cemetery on their trip abroad, expressing their fascination to burial ground as a place of culture, history and architecture.

Structure of the two burial grounds

Analysed cemeteries differ in size. Prazeres, occupying 0.12 sq.m, is almost twice smaller than Alto de São João cemetery. This area responds to the permanent sepulchers area in Alto de São João cemetery. The rest of the Alto de São João cemetery is dedicated to the temporal burials.

At the first glimpse, one can notice that both cemeteries' central structure is defined by orthogonal grid, based on the cross like relation between the entrance and central chapel, expanding its "rays" in three points, shaping the cross, reminding of *cardo* and *decumannus* (Figure). There is another element that resembles a structure of a Roman city – a wall that surrounds almost every cemetery of European tradition. This wall – a frontier of symbolical protection from the dead, and physical protection from the living – differs in height from one tradition to another. In case of these two cemeteries in Lisbon – it is a tall, sometimes 5 m height structure, impossible to surpass. It is expected to discover this cross like structure highlighted after processing Depthmap analysis.

Figure 3. The root of Alto de São João cemetery and Prazeres cemetery is a cross structure with a chapel in the center, serving as the most sacred element of the burial ground. The structure gets more profane when getting away from the very center .

⁴³ Estimation obtained from googlemaps.com

The rigid central structure defines the rule of the further development, however in the case of Alto de São João topographical conditions might have implied the further decisions of the planner when designing the outer structure for temporal burials. Simple identification of axes of the cemeteries lead to understanding the level of a homogeneity of the cemeteries (Figure 3).

Figure 4. Axial system of main pathways in Alto de São João and Prazeres cemeteries.

Alto de São João structure reveals two different types of organization – orthogonal at the core and spontaneous-organic structure at the Eastern outskirt. How these parts of cemetery differ in function and price? Is there any social difference between the “clients” of these parts?

Figure 5. Alto de São João cemetery is composed of permanent (light grey) and temporal (dark grey) burial grounds. Prazeres is entirely permanent.

The structure of the Prazeres cemetery coincides to the core plan of the Alto de São João burial ground, and has no visually identifiable suburbs, except the southern part, that reveals to be less connected to the central part.

Orthogonal structure in two burial grounds share the same kind of land use – in Prazeres they are all occupied by private *jazigos* (chapel houses) and permanent graves (light grey colour in Figure 4), while in Alto de São João part is exclusively dedicated to permanent burial, while organic structure of suburbs is all used for temporal burial (dark grey colour in Figure 4). Temporal burials appear in the orthogonal structure surrounded by private *jazigos* (chapel houses), columbariums or municipal *jazigo*, this way isolating the temporal burial grounds, and sometimes turning their “backs”, giving the space a feeling of harshness and austerity (Figure 5). The reality reveals a formula neighbourhood&community (Figure 6) vs. desert&austerity (Figure 5).

Figure 6. Temporal burial ground in Alto de São João cemetery with the back walls of public ossuaries.

Figure 7. Private *jazigos* are mostly organized in orthogonal grid.

Space syntax study

Space Syntax analysis is carried out for two burial grounds in Lisbon for understanding how each spatial structure of the burial ground is related and connected to others. The focus is on the possible social stratification inside the cemeteries expressed through the spatial organization. The data retrieved from Depthmap is to be cross connected to cemetery service values that serve as an indication of certain social groups using certain part of a burial ground.

Burial ground as a typology is a segregated element in the city fabric. It is separated by the wall from the rest of the surroundings, in case of Alto de São João and Prazeres wall in some points reaches 5 meters. Both burial grounds only have one entrance each that segregates them even more from the urban context. It is like a city in the city, protected from the exterior world by the walls, as a kind of Roman city with a notion of danger of the exterior world, of the unknown. It is like a closed condominium, with guards at the entrance, or a prison, or a hospital – it is an institution that cannot be entered whenever one wants. It is a territory with rules, visiting hours, prejudices and myths, with lots of worries expressed by the ones who visit and the ones that will “inhabit” it in the future.

Different levels of interior segregation can be observed in the “interior” of the burial grounds. In figure 3 Alto de São João shows a combination of two grids – orthogonal and organic-spontaneous, while Prazeres has almost homogenous orthogonal grid, only with one change of direction.

Figure 8. Integration HH axial map shows the most integrated parts of the cemetery (the thickest lines). Alto de São João cemetery has a more expressed center and several sub centers. Prazeres cemetery holds most integration in one line.

Axial map uses a scale of lines that differ in their thickness, where thickest line is used for the most integrated lines, and the thinnest ones for the least integrated lines, varying as well in black to grey tones.

In the structure of Alto de São João the spectrum of values of levels of connectivity reveals almost “one colour” plan – meaning that most of the lines are of alike values. Structure of Prazeres, even though revealing more homogeneity in plan, has a hierarchy of connectivity values, with the most connected path in the back of territory, stretching in the direct line.

The level of integration of a burial ground structure can give hints of how this kind of built environment functions socially, indicating existence of the social stratification of a certain level.

Table 3 presents the integration values with a burial options found on the pathways of certain level of integration in Alto de São João burial ground. Temporal graves only appear on the second most integrated pathways (average thickness and grey colour in the plan). These temporal graves, however, are hidden inside the “neighbourhoods”, surrounded by private *jazigos*, that beyond the service price of burial, implies the value for land concession and construction of *jazigo*, or acquisition of one already built. Same rules are applied for perpetual graves, values for land concession are presented in the table 2.

In the case of Alto de São João cemetery, while the integration value goes down, temporal graves get further from the entrance and from the nuclear center. The most celebrated and the most expensive private burial grounds surround the temporal graves that are closest to the center, hiding this reality and sometimes even turning their deaf walls to them, as shown in a figure 4. Private *jazigos*, found in the green level of integration make part of homogenous “neighbourhood” that consists only of private *jazigos*. Perpetual graves located in the pathways of lowest integration are surrounded by private *jazigos* as well.

Differences of the urban fabric in Alto São João burial ground lead to different visibility maps retrieved through Depthmap software. The rigid orthogonal grid of three-dimensional sepulchers are visibly less permeable. One can sneak peak into the interior of the little “neighbourhoods” of sepulchers, however the proportions of space only allow one looking along the extended visibility lines constructing organized chess-like cemetery fabric. “The right wing” of the cemetery, used for temporal burial, have different qualities – the core is an open vast space and 3 dimensional objects only surround the territory, serving as a wall of the burial ground. There is an appealing difference of space quality and it actually differently affects a visitor. Death is somehow more painful here. There is no caressing and compassion. Death is a fact, a number marking the grave. Its poetry speaks of loneliness, on the contrary to the qualities of the area in the core of the cemetery, that reveals itself as more communal, more “neighbourhood” type.

Table 3. Integration values and burial option with service costs

Line thickness	Integration values	Burial options	Price for service, €
5	1.94 - 1.84	Private <i>jazigos</i>	189,55
		Perpetual graves	145,65
4	1.77 - 1.68	Private <i>jazigos</i>	189,55
		Temporal graves (surrounded by <i>jazigos</i>)	85
3	1.65 - 1.52	Private <i>jazigos</i>	189,55
		Perpetual graves	145,65
		Temporal graves (surrounded by <i>jazigos</i>)	85
2	1.51 - 1.09	Perpetual graves	145,65
		Temporal graves (surrounded by <i>jazigos</i> and open field)	85
		Private <i>jazigos</i> (inside the neighbourhood)	189,55
1	1.08 - 0.53	Perpetual graves	145,65
		Temporal graves (open field)	85

One point eye-sovist graphs show what is visually reachable from one chosen point. The view from the entrance of Alto de São João cemetery ends by the chapel, located 130 m away from the entrance. On the right the view stretches along the columbariums, until it ends by the cemetery wall 370 m away. On the right the view stretches the same distance, however not as wide. These isovists are linear. Analogue shape of visibility at the entrance is revealed in Prazeres cemetery. Eye-sovist and knee-sovist are placed aside since the barriers are of the same origin – three dimension sepulchers and the chapel.

In the open field of temporal graves in the right wing of the burial ground the eye-sovist graph is different – it is open, stretching up wide almost to 360°, eventually bringing to sight the industrial landscape by the Tejo river.

Figure 9. One point eye-sovist from the entrance in Alto de São João and Prazeres cemeteries are the same “T” shape. Inside the orthogonal plan eye-sovists are either linear or cross like (where the paths cross).

Figure 10. Eye-sovist in the temporal burial field stretches almost to 360°. This analysis is processed only to Alto de São João burial ground, as temporal burials are not implemented anymore in Prazeres cemetery.

Final comparison and conclusions

Spatial qualities speak for themselves, and the historical facts, morphologic analysis, data retrieved from Depthmap software and the burial service prices serve for confirming the raised question – at what level social stratification exists in the burial grounds? Can it be confirmed with a quantifiable data?

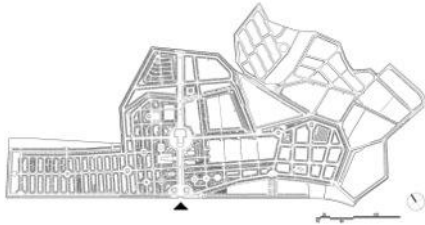

It is concluded that these notions can be confirmed joining historical facts with morphological studies, real estate and service values for burials and graphs retrieved through Depthmap software, based on Space Syntax theory.

Alto de São João burial ground found at the same time as Prazeres cementery, is still in use. It is almost twice bigger, both structures started by kind of *cardo* and *decumannus* combination of paths, still identifiable today. The service prices for burials are the same in both cemeteries, as they are defined by municipality, however Prazeres receives only the ones that already have family burials there or acquired *jazigos* in an auction. Prices for *jazigos* are higher in Prazeres than in Alto de São João. Prazeres is a prestigious cemetery, a celebrated touristic point, praised by historians and art lovers.

Alto de São João cemetery has in its territory a crematorium that is in full function. Both cemeteries are out of urban nucleus of Lisbon, but still in Lisbon territory. Alto de São João is bigger structure, but less public transport passes, and metro is a big further than in case of Prazeres cemetery.

Alto de São João is composed of two kinds of morphological structures – orthogonal and organic (spontaneous), different morphological structures serve different burial purposes. Prazeres is all orthogonal, with on one change of direction, that still continues orthogonal grid. Segregation of an organic part of Alto de São João cemetery is identified by the weak syntactical connection to the orthogonal structure. The far end “east wing” of the cemetery is used for temporal burial, that is the cheapest burial option, accessible for most of social levels. After 5 to 7 years in the temporal burial the bones are taken out from the ground, cleaned and put where family decides – either public ossuary, public columbarium (if cremated), ash field (if cremated) or any other option. Whatever is chosen, the burial service must be paid again (table 1). Prazeres cemetery has no temporal burial grounds, and this type of segregation is impossible to identify.

Table 4. Two cemeteries, founded at the same time, throughout the years developed into two directions, differing in their relation to the urban context and their own spatial organization, serving as well different social classes

	ALTO DE SÃO JOÃO	PRAZERES
		
Year of foundation	1833	1833
Size	0.22 sq.km	0.12 sq.km
Still used for burial	Yes	No (only for special cases)
Price of land concession	Defined by municipality (same for both)	
Price for burial services	Defined by municipality (same for both)	
Price for private <i>jazigo</i> (in auction)	Lower	Higher
Crematorium	Yes	No
Relation to the city	Outside the urban nucleus	Outside the urban nucleus
Distance to nearest metro	1.5 km	1.2 km
Public transport taking to the gate	2 buses	4 buses and 2 trams
Internal structure starting with <i>cardo</i> and <i>decumannus</i>	Yes	Yes
Internal structure	Orthogonal and organic (spontaneous)	Orthogonal
Space syntax results - integration HH (segregation)	Segregation identified	Segregation not identified
Temporal burial grounds	Yes	No

The continuation of the research

Continuing this approach to morphological studies of cemetery design, more cemeteries must be studied for either confirming or denying the question of social stratification of a burial ground. Therefore questionnaire will be handed for more respondents for understanding what mostly disturbs and caresses people in cemetery – a place of both personal and public memory, as well as their relation to the cemetery as a place of intimate relation of the passed away – are they visiting it for celebrating the life of their dear ones, or they live the memories in other places?

The comparison made in the paper joined axial map data with burial service values. It would be useful to take into account average family savings of the minimum income in Portugal. It would let to understand which burial option they would more likely acquire. What is more, a questionnaire for the family of minimum wages could include the question about their burial options.

In relation to social stratification in the cemetery, it makes sense to analyse the historical development of Alto de São João cemetery for understanding how temporal burial were planned throughout two centuries.

U+D urban form and design. A tool of Urban Syntax to design

Paolo Carlotti

Lab. Progettazione architettonica, Università di Roma "Sapienza",
Facoltà di Architettura– DIAP. Email: paolo.carlotti@uniroma1.it.

Abstract. *It's time for a reflection about architectural design through European geographical's thought of the late nineteenth century (LEIGHLY, 1965), developed further especially in English and Italian cultures and particularly in urban morphology (urban morphology – Conzen) (Conzen, 2012) and architecture design (building typology – Caniggia) (Caniggia Maffei, 1979). This subject, initiated by Richter and Ratzer's thesis, advances to the primary synthesis with the idea of "region" by Vidal de la Blanche, and afterwards with the Sauer's idea of landscape as an "organic body" (Sauer, 1925). Later it was improved by Conzen in urban morphology's field, and Muratori and Caniggia in the field of architecture relatively to the concept of "tipo". Morphology and architecture, landscape and building process are, actually, complementary scientific fields, essential for designers of historical landscape (Nevter, 2009). Several research and comparative studies between these two schools, have been the focus and a field for reflection. This has produced some major studies like that of space syntax (Marcus, 2011). Landscape and historical spaces are texts that one should learn to read (Strappa, 2011), with this point of view the tissue and the urban body are words of a paper written by many authors, that shall be interpreted. They are like sentences and words of a collective work to be interpreted in order to build a grammar and syntax for architectural and urban design. U+ D wants to bring the Italian exception (typological analysis-Muratori-Caniggia) to a wider international discussion of urban morphology and in the same time it wants to emphasize the architectural aspect of this theme, which is essential for further and more effective architectural design dimension.*

Key Words: Urban form, urban syntax, design

The european roots of cultural geography

"The systematic organization of the content of landscape proceeds with the repression of a priori theories concerning it. The massing and ordering of phenomena as forms that are integrated into structures and the comparative study of the data as thus organized constitute the morphologic method of synthesis, a special empirical method. Morphology rests upon the following postulates: that there is a unit of organic or quasi-organic quality, that is, a structure to which certain components are necessary, these component element being called 'forms' [...]; that similarity of forms then being 'homologous' and that the structural unit may be placed in series, especially into developmental sequence, ranging from incipient to final or completed stage. Morphologic study does not necessarily affirm an organism in the biologic sense as, for example, in the sociology of Herbert Spencer, but only organized unit concepts that are related." "[...] there is a unit of organic or quasi-organic quality [...]" (Sauer, 1925).

1925, Carl O. Sauer spells out scientific theory of urban morphology, argues the study of physical space by systems orderly within a process in which man and territory are included in the unit. System, organism and process inaugurate, from the beginning of last century, the time when these terms beginning key words among scholars of territory and landscape. Between those have tried synthetically to explain the character of human environment within interrelation of material quality and cultural capabilities.

Ritter, Ratzel, Vidal de La Blanche, Davis, Boas, Wissler, Demangeon, Passarge, Lehmann are, from the beginning of nineteenth century, among the earliest scholars to operate in disciplinary field divided between those who stiffly defines the physical surroundings decisive for human component and whoever later shall reduce the value, within interrelation of material

quality and cultural capabilities, from absolute to relative. Later others will spend time and effort trying to specify and to point out reasons and values of transformation process notion's, but despite this, few will be able to supply adequate and exhaustive useful indications for architectural and urban design. In several cases, these are suggestions made on surveys intuitive or derived from studies on border line architectonic field that rarely goes into the merits of the systems and anthropic physical structures with the typical tools of architecture.

Leighly in 1965 (Leighly, 1965), in an interesting anthology of writings by Carl O. Sauer, emphasizes the elements that have helped to establish the theoretical formulations, the cornerstones of urban morphology. It is begun by Otto Schluter (Whitehand, 2007) and for a few decades raised to field for urban study, then from purely geographic area it's relocating to the pragmatic professional architectural.

In fact, It is common conviction among those who deal of territory that the morphology and the physical character (altimetry, hydrometry, etc.) influence the history and evolution of the urban landscape. "[...]l'individuazione dell'identità territoriale (alle diverse scale della regione e del singolo luogo è fondamentale per avviare processi di riterritorializzazione (riappropriazione dello spazio ndr). Questa individuazione richiede la lettura del processo di formazione del territorio nel lungo periodo per reinterpretare invarianti, permanenze, sedimenti materiali e cognitivi in relazione ai quali produrre nuovi atti territorializzanti.

Ogni ciclo di territorializzazione, riorganizzando e trasformando il territorio, accumula e deposita una propria "sapienza ambientale", che arricchisce la conoscenza delle regole genetiche, contribuendo alla conservazione e alla riproduzione dell'identità territoriale attraverso le trasformazioni (distruttive e ricostruttive) indotte dalla peculiarità culturale del proprio progetto di insediamento."

"[...] l'analisi storica del processo di formazione del territorio non è finalizzata alla ricerca-conservazione della "natura originaria" del luogo (genotipo o memoria genetica) ma all'individuazione delle sue buone pratiche riproduttive che forniscono regole (costruttive, insediative, relazionali) per proseguire l'opera di territorializzazione secondo criteri e forme innovative[....]" "[...] l'analisi non è finalizzata né a trasformare il territorio in museo, né a copiare stili; ma ad acquisire sapienza ambientale e arte di edificare che hanno creato, in epoche precedenti, relazioni virtuose fra insediamento umano e ambiente e utilizzarle per il progetto di trasformazione." (Magnaghi, 2010). Despite of all these efforts is sufficiently clear to most people, and like this writing Magnaghi points out, what is the node to be tackled in order to contribute effectively to the development of the knowledge accumulated. It should go into the "environmental knowledge" is not so much from the theoretical point of view, rather than the operational level of development, including the diachronic analysis and urban morphologies. This operation today is certainly more difficult to recognize than in the past for amount of layers and architectonic structures and urban areas that are superimposed. The acceleration of the process of transformation of the territory in general and Italian in particular, has upset the "spontaneous" metabolising capacity, that human infrastructure had regularly expressed at each stage of the process of transformation on the landscape. The structure is achieved continuously overwhelmed by other anthropic structures, by disconnecting the physical context, produce fragmentation of the urban system, disarticulate content in the urban unit of the institution, sometimes irreversibly damaging the whole. From the organic unit it switches to the juxtaposition of heterogeneous and serial elements so in the expression as in the economic and social function.

The request disciplinary, especially the fields that deal with the design of the territory, it shall notify the urgent need for new rules to study the transformation process so as to restore valences and meaning nodality extensive and peculiar to the territory and urban centers otherwise destined to remain satellites of the large agglomerations or sentenced to abandonment.

U+D urbanform and design aims to be a space for reflection to accept even the disciplinary point of view of human geography in its contemporary paradigms (Vallega, Vagaggini, Corna Pellegrini, Quaini), which coincide (with the idea of type and process concept and history

operating of the Roman school of urban morphology) with the idea of human space and geographic complex, the product of evolutionary processes and involutive of cultural areas, or parts of them, which contribute and have contributed to define a new unit to larger scale. The limited range of human geography and urban geography in particular, as a representative form of the collective imaginary gives particular importance to the relationship between physical components and the main anthropic structures intended for to displacement, settlement and conomic productiones (Wissler, 1965). Elements used also by Gianfranco Caniggia in the synthetic representation of the territory. A position that is in fact agree geographers and architects of the territory and which has led us to confirm such as particularly useful representation of these elements to describe the territory nodes (settlements), axis (paths), areas (production areas) and lines (boundaries).

The italian school contribution and new tools and elements of reflection

It also wants explore significance synchronic and diachronic in Urban Syntax and in drawings of the territory. Those who Caniggia had already graphically synthesized in the phases of the formative cycle of the territory, which begins with the phase of the ridge and ends with the step of the valley.

Now, although the concept of culture area is now common knowledge, the connection of this with the physical characters (borders, usable areas, structures for the movement and anthropic elements for settlement), shared and assumed in the domain of human geography and its related fields is still fuzzy in the design perspective, however, this seems recently emerge more clearly from the domain of the sciences of architecture. Gianfranco recovering the regional synthesis of Saverio Muratori published in the book *Cività e territorio* (Muratori, 1967) had summed up in a few but significant marks central places, already proposed as significant elements of cultural regions recognized in the territory by Smile and Dickinson in 1947 (SMILE 1947, Dickinson, 1947). He had introduced the design theme that was missing in the geographical field; something which in fact was distilling in these disciplines alike to architecture they had in common the natural environment (in which there are the territorial and architectural. design), its understanding and its representation in phases and for regional areas geographically homogeneous and cooperating.

The projective intuition of these studies is the result of the progression of interdisciplinary knowledge, which developed within a European geographical line of thought binds Otto Schluter with Carl Sauer, Vidal de la Blanche Lucien Febvre and Fernand Braudel, and which find continuity in the school of urban morphology Anglo-Saxon and North American (Conzen, Whitehand, Moudon, J.Conzel, Larkan), and for urban and regional project showing interesting elements in results achieved by research and reflection of the Italian school. School that registers a growing consensus (University of Laval, Portland, Utah, Birmingham, Porto, etc..) and receives strong encouragement in the field of design, at the international level.

Limits and boundaries are identified on the maps and cadastral tools. They vary in time and space. In a subsequent phase they may appear, values and hierarchies, the opposite way to the previous one. Organization and roles of the components are constantly changing from the sites more easily umanizabili (ridges) to the less antropizzabili territories (valley). All in all this trend is gradually increasing the extension of the cultural area and at the same time it is articulated, at the local level, in sub areas qualitatively significant. The study of the formative processes of the urban fabric of the historical cities of the youngest cities in Europe and America and Asia (Davis H., 2013), suggests the idea of a reflection space oriented towards the approach of the scientific analysis of the physical forms of nature and landscape A disciplinary field that involves the geographic and architettura domain, a field of study and experimentation still undefined at the boundary between the Space Syntax (Whitehand J., 2007) and the urban morphology.

The overlap of marks, forms that make up the urban design it is now well-established field of study of urban morphology (Kroft, 2014). Concepts such as range or boundary dividing relevance (Conzen, 2013), in the description of the relationship built between the path and lotto is commonly used in the school of geography in Birmingham (Whitehand, Conzen) and in schools of architecture like Laval (Moretti) in laboratory of urban form on the shape and the process of the urban fabric in Lisbon (Diaz). While the confusion of the signs as an expression of economic, political, morphological factors is object of scholarly attention of Space Syntax, it seems to sketch, in dimension of the Urban Syntax as a grammar of a three-dimensional text and collective work.

the renewal of relations between geographic and domain historic (Maffei, 2014) has always been upstream of the urban process, of the study on building characters, on analyse of type aimed at project (Strappa, 2014) it seems emerge as the Rosetta Stone in understanding "architectural text. "

Lines and shapes of the urban space and territorial, still shrouded in the fog of the chaos that seem to emerge from the apparent confusion such as words of layers superimposed traces of a collective work, composed by a grammar still largely to be encoded and the story which we believe is can change, sometimes intentionally amazing but mostly by continuing the process that generated them.

U+D urbanform and design is an online magazine dedicated to architectural and urban design. Its an utility open to scholars and architects involved on the project summary of the process connected to the urban morphology of the city and the region. Wants to offer an interdisciplinary space between urban morphology and building typology design dimension. He wants to reflect and offer the space for the comparison of architectural projects in the continuity of the idea of intentional or unintentional process, the shape of the space in its results and in relation to contemporary traces of material culture inherited recognizable in their unitary character stays in the residuals of masonry and organized on knots and cultural areas of different temporal phases.

The evolution of house forms and the change of culture: a Turkish perspective

Duygu Gokce, Fei Chen

Liverpool School of Architecture, University of Liverpool.

E-mail: duygu.gokce@liverpool.ac.uk.

Abstract. *People continuously modify their living environment to improve their life quality. This has been done in a piecemeal manner traditionally where the physical forms could be gradually adapted to meet the change of life-styles. However, rapid transformation of cities in the modern age has caused incompatibility of physical forms and the local culture. It is therefore important to study the dynamic link between house forms and the residents' everyday life and needs over time. Within the Turkish context, this paper will explain the change of Turkish house types within 5 different morphological phases when external influences have been in effect. The spatial arrangements of each house type will be analysed through case studies and special attentions will be paid to the everyday use in those houses and the relationships between private, semi-private and public spaces. The conclusion will be drawn on the house form in relation to people's way of living and will shed light on socio-culturally sustainable development and regeneration in contemporary Turkey. This paper will also contribute to the argument for a positive impact of typological processes of physical environment on the local culture.*

Key Words: House form, spatial organisation, residential satisfaction, quality of life

Introduction

Since people interact with each other in spaces, their satisfaction with life depends on their relationships with the constantly changing built environment. As Ozaloglu (2006, p.75) indicates, 'life style and physical environment do not change simultaneously'. Physical conditions can be easily changed; however, even if these conditions are positive, they might not meet residents' genuine desires after change (Cheung&Leung, 2008).

This impact has become more prominent in contemporary built environment, because the concept of type, which was introduced as a social and cultural tool by Gottfried Semper in the 1830s (Chen&Thwaites, 2013), has lost its power in contemporary world and people have become less socially and culturally connected to their living place. In this study, the term 'type' refers to housing types, presenting similar characteristics in terms of functional zoning, spatial organisation and public-private area relationships; and 'typological process' refers to the continuous transformative changes of these house types.

To understand the relationship between a house type and the inhabitants' life style, internal layout of the house type and its relation to the surrounding are important parameters to examine, because people organize their surroundings based on their living habits and the intervention to the organisation of space can easily affect their life styles. Specifically, spatial relations in Turkey can be represented by the relational structure among private, semi-private and public spaces. This is because the concept of social interaction derived from nomadic life style and the concept of privacy changing after adoption of Islam (Yildirim & Hidayetoglu, 2009). Therefore, privacy and social interaction are the most important factors that should be considered in the investigation of the impact of spatial relations on residents' life style and quality in Turkey.

This paper focuses on the relationship between spatial organization and people's life styles over time in the Turkish context with special reference to five house types chosen from the capital city Ankara in five morphological phases from the late Ottoman Empire period to the present. These house types will be analysed based on their spatial arrangements and the relationships between private, semi-private and public spaces in order to explain how the

physical housing unit fits to its residents' life styles. The conclusion will be drawn on the house form in relation to people's way of living and will shed light on socio-culturally sustainable development and regeneration in contemporary Turkey.

The evolution of house form in Turkey

In Central Asia, Turks had the nomadic life style and lived in tents until settled. After the settlement (VII-XIII. centuries), tents have been replaced by rooms (Ozcan, 2005). The different spatial organisations of these rooms have resulted in the emergence of different house types now called traditional Turkish houses. These houses, which have had about 500-year history, have experienced major development along with social, cultural and economic changes and their impacts on housing design have continued until the 1940s despite the recession period of Ottoman Empire in the late 19th century (Yildirim ve Hidayetoglu, 2009 and Eldem, 1975). However, the growing relations with western countries in the second half of the 19th century have resulted in the emergence of new house typologies (Sey, 1998a; Sey, 1998b).

In 1923, Republic of Turkey replaced the Ottoman Empire. Despite the significant housing shortage, the first years of the Republican period were a period of stagnation in terms of housing construction because of economic problems after the WWI (Sey, 1998b). Despite the desperate housing shortage and the introduction of apartment buildings called rent houses (Guney & Wineman, 2008), the ideal housing types were still single-family detached houses (Guney & Wineman, 2008). Therefore, it was still possible to see gradual extensions of historic residential areas (Osmay, 1998). Moreover, the 1930s was the period when apartmentalisation was criticised (Balamir, 1994) to have ignored the traditional Turkish life style by offering flats to everyone without considering social, cultural, economic differences and forcing them to live on top of each other (Kansu, 2009). Therefore, garden city house type became the alternative; however there has not been a significant increase in the number of houses due to economic constraints (Sey, 1998b).

The emergent problem in the period of 1950-1980 was the extensive construction of informal houses (Batuman, 2006; Sey, 1998a). As an initial response to these slum developments, apartment buildings, which were generally 3-storey and with two flats per floor (Toker & Toker, 2003), were offered (Batuman, 2006). Afterwards, large scale mass housing projects and multi-floor apartment buildings were extensively implemented; however, this caused the replacement of garden houses by apartment blocks (Sey, 1998a; 1998b). In this period, there was no determination in the construction of similar house types because of the emergence of various types of apartment buildings and their extensive construction. Furthermore, there have been important social changes due to the promotion of apartment life style.

The early 1980s was the recession period of housing production because of decreasing demand for housing as a result of the financial crisis and there had also been a significant decline in the ratio of slums by introducing new housing regulations as a result of expanded liberal economy policy (Turel, 1989). From the mid-1980s, the housing production has dramatically arisen (Turel, 1989) and the housing cooperatives became more dominant in the construction of collective houses until the 1990s (Sey, 1998a). In the late 20th century high-rise apartment buildings have become dominant (Toker&Toker, 2003). Apart from these projects, there was a new form of housing complexes—gated communities, called '*site*' in Turkish and whose target group was high-income groups (ibid) and the aim was to increase the QoL with the preservation of historical, social, cultural and natural resources and the national identity (Tapan, 1998).

From the 2000s, the emphasis has been given to urban regeneration projects due to rapid increase in the number of slums in Ankara (Dikmen, 2012). Mass housing projects consisting of an isolated group of apartment buildings which are at least 5-floor or more and usually linearly arranged in a plot and the borders of which are clearly defined have continued to be

implemented. Currently, this type of housing is still the most popular type of collective housing.

Case studies

From the general description of the evolution of house form in Turkey, five morphological phases can be identified: The late Ottoman Empire period (1890-1923), the early republican or modern period (1923-1950), industrialization period (1950-1980), liberalisation period (1980-2000) and the contemporary period (2000s). Similar phases are acknowledged in literature by various researchers (e.g. Ataov&Osmay, 2007; Ozbek-Eren, 2012; Tekeli, 1998). These phases represent the periods when different external influences have been received. This study analyses these phases under three sections: Traditional, transitional and contemporary (Figure 1).

Figure 1. The categorisation of the morphological phases.

The investigation of the evolution of house form under economic, administrative, social and cultural changes starts with traditional single family houses, focuses on how these houses have developed over time and transformed to apartment buildings in contemporary Turkey.

The traditional period

The design of the traditional Turkish houses developed based on two main elements: rooms and a hall (called '*sofa*' in Turkish) (Tavsan and Sonmez, 2013; Oztank, 2010). It is acknowledged that despite the variety, there are three main types of traditional Turkish houses showing differences based on the location of the '*sofa*': with outer hall, with inner hall and with central hall (Figure 2).

Figure 2. The main traditional Turkish house plan types determined by different arrangements of Rooms and the Hall (Oztank, 2010, p.273).

The hall in all types was not only a passageway but also a place where residents and/or guests interacted with each other (Tavsan & Sonmez, 2013). As the traditional types transformed, *sofa* had turned to an interior space serving as a living room, which directly opened to the rooms. Each room was designed to serve one nuclear family and the extended family shared the entire house. Every family member had to pass through the *sofa* to access his or her more private family rooms. One or two sides of these rooms generally project outwards

from the outside wall of the ground floor [Fig.2c] to expand the view and increase the control over public realm by looking at who came to the house through the narrow windows located on the projected side wall (Yildirim & Hidayetoglu, 2009). Overall, therefore, traditional spatial arrangement has played a key role in creating opportunities for social interaction and protecting privacy at both family and social levels.

Figure 3. The relative organisation of private, semi-private and public areas in traditional house developments (By author).

The importance given to privacy was also evident through the relationship between a housing unit and its surrounding because of Islamic rules. For instance, these houses had at least 2 floors and there was limited interaction with the lower floor, and the main living space was usually on the upper floor (Tavsan & Sonmez, 2013). Moreover, the size of windows was smaller on the ground floor than that of the first and/or second floor. The connection of the house to the public realm was provided by private and/or semi-private walled-gardens around the house [Fig.3].

Regarding traditional Turkish neighbourhood structure, neither buildings nor streets were randomly organized. Even though the houses were designed individually, they were respectful to each other and became a part of a whole. Houses and streets always defined boundaries in both 2 and 3 dimensions (Oktay, 2004). For instance, streets were hierarchically ordered based on inhabitants' needs, which was achieved through organic street development from the main streets to narrower ones and ending up with cul-de-sacs (Oktay, 2004).

Overall, the traditional housing formation at building, street and neighbourhood scales has been designed strongly depending on the social life style. Currently, it is widely believed that the traditional Turkish houses were the best house types which have satisfied the needs of the Turkish people for centuries in terms of having an appropriate shape and plan based on the life style, culture and morals of the traditional Turkish family (Oktay, 2004;2002). It can be predicted that the reason for this achievement lies behind the naturally established relationships between private, semi-private and public areas at both small and larger scales.

Transitional period

Transitional period presents the housing developments from 1923 to the 2000s under 3 sub-periods. This section will analyse 'Bahcelievler Housing Cooperative' in the period of 1923-1950, '14 Mayıs Houses' in the period of 1950-1980, and Apak Housing development in the period of 1980-2000.

Bahcelievler housing development

Bahcelievler housing development planned by Hermann Jansen in 1934 in Ankara was the first garden city in Turkey and has been actively used until the 1950s (Kansu, 2009; Yalcinkaya, 2007; Ucar, 2005). After the 1950s, the settlement has undergone rapid urban transformation (Yalcinkaya, 2007).

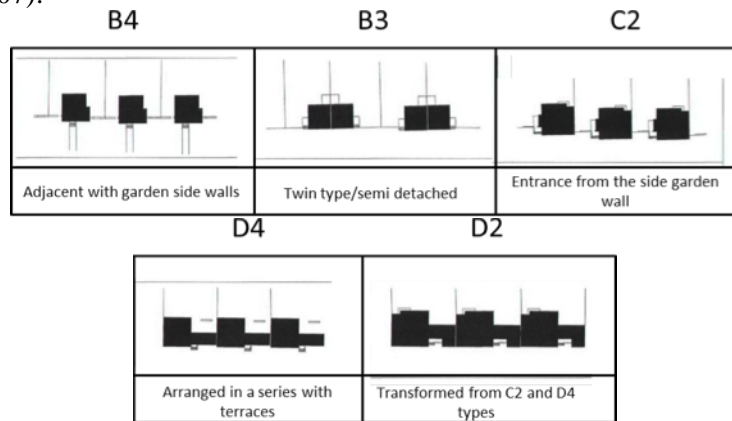

Figure 4. Bahcelievler Garden city house types (Adapted from Ucar 2005, p.101).

The development consists of five house types: B4, B3, C2, D4 and D2 [Fig.4]. B4-type houses, which were mainly located on the south of the site, were the majority of the settlement [Fig.6]. As an individual unit, this house type had two-floor with level entry onto the lower floor: The living room and the kitchen were located on the ground floor and the bedrooms were on the first floor. The separation of day and night activities was new for Turkish people.

Figure 5. B4-Type House layouts (Adapted from Ucar, 2005, p. 104).

The accesses to these function areas in both floors were provided via a hall. Unlike in traditional houses, the hall was not a common room anymore but only a passageway. Nevertheless, the hall is still an important part of the housing layout, centrally located and separated from the entrance. It was essentially different from the entrance halls or short corridors in English garden houses. The location of the living room allows the residents to have control over both the street side and the garden side. The living room was designed as two sections separated by a glass panel door, which allows residents to customise the living room depending on changing daily activities. For instance, when they have guests, they could turn the back half of the living room into a bedroom or if one of the family members is an elderly, this

room generally given to him/her because of its privacy and ideal location to other functional areas of the house.

The entrance to the houses is directly from the street through a front garden, which is more public and there is a back private garden accessed through the house from the kitchen balcony on the ground floor and through a secondary side entrance [Fig.5]. This also contributes to the natural connectedness. Privacy is also important in these houses. The garden walls on the street side are higher and there is a clear separation between front and back gardens. The residents can both benefit from social and environmental contact and have more private family life away from the public space.

All house types are linearly arranged along the streets and have their own private gardens at the back. They were detached houses located close to the street side in individual plots; however, there was a continuous façade pattern formed by the erection of pergolas between two houses, which has well defined the borders of the street (Ucar, 2005). Although the built up density of the site is low, the adjacent arrangement of houses along the streets gives the feeling of living in a high-density area. The narrow streets contribute to this feeling. It can be interpreted that this connectedness gives the site a distinct neighbourhood identity.

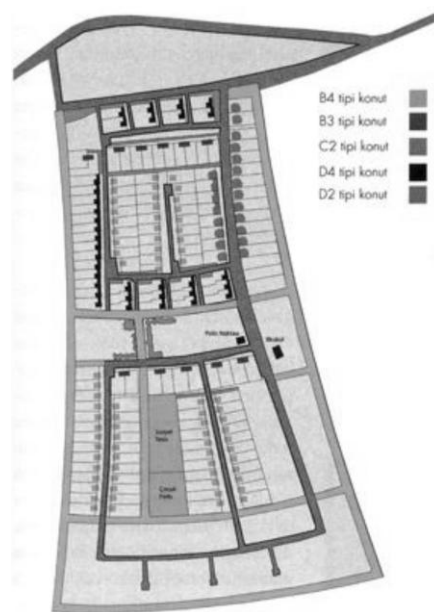

Figure 6. Bahcelievler Housing development site plan 1938 (Kansu 2009, 5).

Although these houses were introduced to promote the modern nuclear family life style as an ideal, extended families inhabited the homes and sustained their traditions because the 1930s was the period when traditional life style was still dominant and familial relationships were still strong. Thus, families were more likely to occupy the house differently than the layout suggested. However, the introduction of the functionally defined rooms has resulted in the integration of western oriented family life style and the traditional ones. Despite this, by the late 1930s, this new housing type has been adopted as an appropriate model of housing for Turkey, interestingly for all social classes (Kilinc, 2012). This might be because they could, unlike rent apartments, offer natural connectedness and similar hierarchical relations between private, semi-private and public areas despite the fact that they did not offer the same spatial and functional organisation at building scale. In terms of street layout, this new type had offered more regular and rigid street layout compared with the traditional network. However, the connection of the each house to the street by a common front garden and small entrance balconies provided the desired level of social interaction and helped develop neighbourhood relationships. Overall, this new housing type was not a direct importation and deviated from its European counterparts;

what is more, they were good at fostering a more common life at both family and neighbourhood scales.

14 Mayıs Houses

14 Mayıs houses are the important housing developments reflecting the concept of the housing in the period of 1950-1980. The settlement was constructed in two stages in the years of 1951-53 and 1958-59; and consisted of two main house types [Fig.11], which have undergone functional, social and spatial transformations until today (Belli & Boyacıoğlu, 2007).

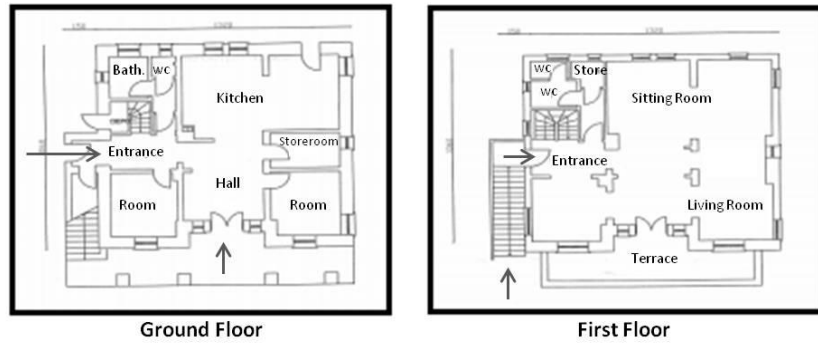

Figure 7. 14 Mayıs Houses Type 1, Ground and First Floor Plans. (Adapted from Belli ve Boyacıoğlu 2007, 721)

The functional zoning in Type 1 is distributed over two floors as in Bahçelievler houses and the function of each room is defined unlike traditional houses. However, the location of the rooms around a central hall reminds the traditional housing layout and shows that the view towards outside is also important for the residents.

Similar to traditional houses, the living room is located on the second floor and the view is extended with the use of the terrace at the front facade, which imitates the projection of the rooms on the first floor like bay windows in traditional houses. Bathroom and toilets are accessible through a separate corridor from the entrance differently from the traditional and garden house types. It is also important to point out that there is still a clear separation between the entrance that is the first contact place to home and the hall.

Figure 8. Type 1 May 14 Houses Garden-Entrance relations (Tanidik, 2005).

Type 2 has two storeys and one flat on each floor accessed through a semi-public staircase, which is a transitional space between public realm and the more private entrance halls [Fig.9-10]. The hall called ‘sofa’ in traditional houses is not an important design element anymore and has turned to a single entrance hall that leads people to the sitting room, toilet and a secondary hall. Private bedrooms and bathroom are reached from this secondary hall, also called night hall. Therefore, the house has a dual usage due to corridors providing alternate routes from different zones within the house.

Figure 9. 14 Mayis Houses Type 1, Ground and First Floor Plans. (Adapted from Belli ve Boyacıoğlu, 2007, p.722).

Figure 10. Type 2 May 14 Houses. (Belli & Boyacıoğlu, 2007).

It can be understood from clearly defined different sections within the house that nuclear family life style has been adopted; what is more, personal privacy has become more important than the family privacy which was more important in traditional houses. This also shows how the concept of privacy has changed and how this is reflected by the housing design.

Figure 11. Site Plan (Belli & Boyacıoğlu, 2007).

Both types are located in individual plots with an entrance from the street. While the Type 1 is more protected with high garden walls [Fig.8], the Type 2 is more open to the public [Fig.10]. The whole settlement consists of the linear arrangement of the plots and is low-rise medium-coverage similar to Bahcelievler Housing Development [Fig.11].

Overall, Type 1 has offered both traditional and modern life style characteristics, while Type 2 as a modern version of Type 1 has promoted apartment lifestyle. It is clear that there have been a significant shift from extended families to nuclear families with the introduction of new housing layouts and spatial organisations. Moreover, a transition from single-family housing units to low-rise multi-family housing units has been succeeded in this period. Therefore, this period can be considered as a period when apartment living has been adopted as a life style, which has an impact on both social and family life style.

Apak Housing Cooperative

From the 1980s, apartment blocks have become dominant housing types developed by the increasing number of housing cooperatives (Balamir, 1994). One example is Apak medium-rise medium-coverage housing development completed in 1993.

Each flat consists of a single entrance hall as in Type 2-May 14 houses; however, it is large enough to receive/send guests. This is because it directly opens to the living room, which is the largest room generally, used to host guests. There are three other rooms used as a sitting room, a master bedroom and a children bedroom; and the hall plays a key role as a transitional space between them. There is no clear separation between day and night uses of the house unlike in Type 2-May 14 Houses; however, there is a secondary corridor connecting to the entrance hall via a door and defining the private section of the house such as the bathroom and the master bedroom. Except this private section, the rest of the house is quite integrated, flexible to change and actively used during the day.

Figure 12. Site entrance.

The high integration level provided through the halls within the house also helps to customisation of the space based on the needs. For instance, the living room which was firstly only used to host guests, has been used as a living room nowadays depending on the size of the family and the need for an extra bedroom or a study room. However, this has also caused changes in family relationships and individuals have given more importance to their personal privacy in their own private rooms and have become less socially interacted with other family members which is currently criticised.

Figure 13. Typical Floor Plan.

Figure 14. The defined spaces between apartment blocks.

The flat also has three balconies one of which connects living and sitting rooms and is larger than the other two. The main balcony overlooking to the courtyard contributes to social interaction within family members and/or guests in summer; however, the close distance between the blocks invades the privacy, which also causes the residents to erect PVC and/or glass panels and blind/curtain systems to protect their privacy. However, the balconies are also important design elements contributing to social interaction with the other neighbours in other balconies and acquaintances passing through the site.

Figure 15. Apak Housing Development Site Plan (www.googlemap.com).

Each floor consists of four flats accessed through a semi-public staircase and the whole block has two entrances on the ground floor [Fig. 13]. The site borders are clearly defined and the access to the site is partly restricted by site administration as a gated community.

The complex consists of identical 8 five-floor blocks linearly arranged in two rows with a courtyard in between [Fig.15]. Each building faces both the street side and the courtyard side, which gives an opportunity of having both environmental and social contact and natural connectedness for residents.

Overall, although this development consists of isolated apartment blocks, it creates the opportunities for social interaction in terms of both site arrangement and house layout. Therefore, the spatial organisation contributes to life style of the residents, however, at the same time invades the privacy and promotes the individualisation which results in changes in family and social relations.

Contemporary period

From the 2000s, the construction of gated communities has continued; however, the new developments are generally high-rise, low-coverage, mixed-use housing developments. One example is 12-floor 'Anatolya İkizleri' (Anatolian Twins) constructed in 2007.

In terms of internal layout, similar to the Type 2-May 14 houses, the flats are rigidly divided into two sections based on the day and night activities. Differently, the entrance is quite spacious and leads people directly to the kitchen, the living room, the toilet and the corridor. The corridor opens to the private section of the house, which includes three bedrooms and two bathrooms. The independence of the sections to each other has resulted in the emergence of a very long corridor, which jeopardises connectedness within the house, and decreases the residents' control over the house. This is because of decreased frequency of use and restricted flexibility of house layout. However, this can be also interpreted as a good design feature for the desired level of privacy.

The balconies are important design elements providing interaction to the outside of the house because of the difficulty in establishing physical contact to the ground floor in high-rise buildings. The balconies are not narrow as in the apartment blocks of the transitional period. Their size is almost close to the average room size and gives an opportunity to host more people.

Similarly to Apak Houses, each floor consists of four flats and the development consists of 2 blocks connecting to each other through a car park and a commercial development. The distance between the tower blocks increases the level of privacy and promotes the primacy of family life. However, social life is restricted by the site development in terms of opportunities for social interaction. There is also no interrelation with nearby developments.

Overall, the introduction of this type has increased the importance given to family life and contributed to introvert life style by ignoring the social context outside and by giving opportunities to host more people inside. Although residents are satisfied with their self-contained flats and their independency, this has been causing important changes in development of societal relations.

Discussion

As can be seen from the evolution process analysed through case studies above, residential areas in Turkey have undergone rapid urban transformation since the late Ottoman Empire period.

In the traditional period, the houses had their unique characteristics in spatial organisation which resulted in rhythmic street layout, dynamic and distinctive view from individual houses, connectedness to nature, appropriateness to family and social life, providing opportunities for social interaction, and hierarchically organised private, semi-private and public spaces for centuries.

The transitional period saw less appreciation of traditional characteristics in massive residential developments, which has caused the lack of vitality and liveability (Oktay, 2004). To tackle with this problem, garden houses offering both traditional and modern housing features have been proposed. However, while each housing block has been designed individually in the traditional settlements, housing has lost its individuality and turned to groups of linearly arranged housing blocks (Erturk&Ozen, 1987). There have been significant changes in housing layouts. For instance, the hall called 'sofa' in traditional houses has been replaced by the entrance-hall combination and has lost its living room function. Moreover, rigid functional zoning has decreased the flexibility and customisation of housing space. Extended families have eventually converted to nuclear families and apartment life has been adopted as a lifestyle. However, despite the incompatibility between the suggested layout and the life style, there were still traditional housing characteristics in early apartment examples. Inhabitants were also open to alter their space usage based on their needs even if they were not offered by the housing developments.

In contemporary period, these changes have become more prominent and standardization has forced residents to adapt themselves to the physical environment rather than the other way around. The opportunities for social interaction in contemporary housing development have been weakened. The function areas have become less connected and independent to each other. There has been a significant shift from living-centred organisation to transition-centred organisation with the introduction of long corridors. Although privacy is still taken into consideration during this period, the impact of life styles on housing design has been weakened. Natural bonding and its contribution to social interaction have also been less appreciated. The housing developments have been individualised and disconnected to their surroundings.

In terms of typological processes, traditional house types were the ones showing continuous transformation and gradual adaptation to the changing life styles. Garden houses can also be considered as a part of a typological process because of offering similarities to the traditional house form or being eligible to be adapted to traditional life styles. The next group of houses can be seen as transitional types showing inconsistency between traditional and the modern; but at the same time offering a new life style. The last two groups of houses are imitated copies and completely broken away from a typological process.

It is clear that typological changes play an important role in adaptation of life styles. However, as it can be seen from the case studies, the gradual adaptation of physical forms has failed to meet the requirements of changing life styles, and housing developments have become less integrated and less reflective over time. Whereas, according to Rapoport (Bretonne, 1979, p.118), the '*good fit between life style and the environment*', and '*very high degree of relevance*' between people and physical environment can only be achieved when it is used by them '*in very appropriate ways*'. Unfortunately, Rapoport's (Bretonne, 1979, p. 114) concept of 'systems of settings' which refers to the perfect fit between people's life style and the physical settings has been weakened in contemporary housing developments. Whereas, 'the continuity of a culture is closely associated with the continuity of its housing architecture' (Tavsan & Sonmez, 2013, p.60). Therefore, it is really important to sustain the adaptability of physical forms to local culture and life styles.

Conclusion

While some elements of urban form are kept alive, the others may be replaced or destroyed by the new ones over time (Oktay, 2002). Given this, the continuity of types has been broken in the process of transformation. Standardization in planning and design practices has caused the destruction of the uniqueness of places (Oktay, 2004). Especially in the last three decades, these rapid changes have caused the replacement of house traditions by new apartment blocks which are built at a massive scale, with little thought given to family structure and neighbourhood organisation (Oktay, 2004).

Erturk&Ozen (1987) state that currently Turkish housing planning which forces people to live in unfamiliar houses is completely dependent on coincidences and affectation. Given this, it is fairly difficult to mention an ideal housing type that contributes to users' satisfaction and Turkish lifestyle. This requires the reinvestigation of typological processes of house types and their contribution to better QoL. This paper is a part of an on-going PhD research, which deals with this problem and will use QoL indicators to measure users' satisfaction in relation to each house type over time. It aims to prove that gradual and constant typological process plays a key role in developing better living environment.

Athens and military architecture

Sotirios Zaroulas

Politecnico di Milano, Facoltà di Architettura Civile, Via Teodosio 3, 20131 Milano, Italy. E-mail: sotirios.zaroulas@polimi.it

Abstract. *This paper describes the relation between military areas and the form of the current city of Athens, as it derives from the main urban plans and their elements during the nineteenth century and the purpose is to show how the settlement of military areas has influenced the construction of the modern city. In addition, nowadays all these buildings have been left to stand derelict and have become a dual challenge for the city: on the one hand, to manage to reuse this important architectural heritage and on the other to succeed in reconnecting these projects with the city. Through a certain number of plans and an urban scale analysis, the objective is to study the projects of these military areas, focusing on the design, the typology and their settlement principles. In other words, the aim is to analyse them so as to understand the process of their construction and their influence on the evolution of the modern city of Athens. What emerges from this analysis is the fact that the early projects of the barracks during the nineteenth century are closely related to the city plans, the urban elements and the history of the city. Moreover, it's important to underline that even in those cases the military buildings have been demolished, many urban voids have been created that have offered new opportunities for the growth and the expansion of the city.*

Key words: Settlement principles, military building, nineteenth century, urban types, urban growth.

Introduction

Athens when it became the capital of the Greek newborn state in 1833 was a small city shrunken to the foothills of Acropolis with no more of 4000 inhabitants (Travlos, 1960) and its urban limits were extended to a point not further than the roman defensive walls of emperor Hadrian. What came after, during the nineteenth century, was a series of plans for the construction of the modern city. The aim was to provide Athens with the aspect of a European capital preserving at the same time the ancient heritage and proceeding with the excavations into the archaeological areas.

Particular attention was given to the projects of military barracks which were considered as important services for the new city. For this reason were constructed remarkable specialized structures that occupied entire parts of the new city and the models that were followed for these projects derive from the European renovated military building typologies.

The attempt made here is to analyse both the relation of the military barracks with the rest of the city and the way these notable urban areas and buildings have influenced and have determined the form and the growth of Athens.

Through an urban scale analysis of the relationship of the individual military building with the urban organism of six examples of military complexes of the city of Athens, the intention is to identify the settlement principles and the relation between the single element/building and the whole plan/city (Figure 1). This will be an important contribution to the study and to the project of reuse of these areas and buildings in the contemporary days and to the reintroduction of their tissue into the present city.

The analysis considers an interval of time between 1833, the first plan of modern city of Athens and 1997, the moment that the Greek Army returned to the municipality large part of the military area of Goudí, a suburb in the eastern part of the city.

Figure 1. A map of Athens with the barracks and the military areas: 1. The building of the royal palace the current Greek parliament, 2. Kleanthis-Schaubert plan, 3. Leon von Klenze plan, 4. Vasilissis Sofias barracks, 5. Cavalry barracks, 6. Officers School in Pedion Areos, 7. The military area of Goudi.

The first two projects have never been realised, as well as the plans of which they made part, that is, the plan of Kleanthis and Scaubert and Leo Von Klenze plan. The third case, along Vasilissis Sofias avenue, concerns the first complex of military buildings constructed in Athens, the next two projects in Pedion Areos are the first to be constructed at a distance from the city centre, while the last case in Goudi was one of the largest military areas of the Attic Basin.

The city planning proposal by Stamatios Kleanthis and Eduard Schaubert

In the first years after the Independence, different buildings had been used to house the Greek Army; for example Villa Ilissia, the present Byzantine Museum, was the School of Army Officers and only in 1900 when it was transferred to the new buildings in Pedion Areos, did the Army returned it to the municipality of Athens (Biris, 1996). The first organized military structure for the Greek capital appeared in the plan of the architects Stamatios Kleanthis and Eduard Schaubert.

The plan was commissioned for celebrating the union of the city with the rest of the country and the transfer of the capital from the city of Nauplia in Peloponnese to the new site. Even if it

had been revisioned many times by many planners, it has influenced dramatically the form of the contemporary city.

The important element of this plan is its triangular shape, which determines the position of the main elements of the city construction: the government centre, the economic centre and the religious-cultural one. The form of the plan derives from the long tradition of baroque urban plans such as the roman trident, the plan for Karlsruhe and Berlin, the plan of Helsinki and of Saint Petersburg (Venetas, 2001). Particular attention was given to the orientation of the triangle so as the future Athenian citizens to contemplate the ruins, the monuments and the Athens landscape through certain interesting views.

What we should notice here is the relation of the military buildings with the royal palace. The military barracks here are the extension of the government buildings and they contribute to the construction of the city, to its elements and to its architectural elevations (Figure 2). They are positioned onto an axis from east to west and perpendicular to this one of the royal palace; the armoury to the eastern and the barracks to the western part of the plan. The barracks with the other public buildings create a round square which in its turn becomes part of a wider system of round squares and wide roads and consequently part of the whole city plan. The complex of the buildings of the military barracks forms also one of the urban gates of Athens, an urban fortified gate. It therefore substitutes the defensive urban walls and symbolizes the fortification of the city and of the royal palace as well.

Figure 2. Scheme of Kleanthis-Schaubert plan and analysis of the relation between the military buildings and the royal palace.

The revision of the plan and the new proposal of Leo von Klenze

The plan of Kleanthis and Schaubert is considered too expensive and Leo von Klenze is asked to review it. For this reason he draws up a new plan that keeps the shape of the triangle but

reduces the width of the roads, the number of tree-lined avenues and squares and also decreases the area to be expropriated for the archaeological excavations. He favours in this way one type of continuous and denser construction that, according to him, is more suited to a Mediterranean city (Venetas, 2000). It also considers improper the location of the royal palace and therefore arranges the whole government centre from a central location at the foothills of Pnyka.

Although the royal palace is positioned to the western vertex of the triangle and it is not anymore the central element of the whole composition, as in Kleanthis-Schaubert plan, it maintains a strong relationship with the buildings of the barracks (Figure 3). The group of these buildings creates not only a fortified urban gate but even a kind of propylaea for the new “Othonopolis”; they are arranged symmetrically each to other but in a very dynamic way; while one forms an open courtyard reserved for the soldiers and it is combined with a large internal piazza d’armi, the other part with a more complex volume will be used for the officers.

Figure 3. Scheme of Leo von Klenze plan and analysis of the relation between the military buildings and the royal palace.

The route of a visitor to this new city, oriented towards the royal palace, is characterized by a succession of interesting elements; has to pass through the monumental gate/barracks, to walk along the widest tree-lined avenue of the city and to climb up the stairways till the urban government centre of the new Athens.

Once again the plan of Klenze will not be realised and because of the economic difficulties requires further revision. Even if it was not carried out it has affected the same the form of the contemporary centre of the city with narrower streets and less squares. Moreover, this plan and the ideas of Leo Von Klenze for the monumental gate/barracks seems to be in some way the anticipation of its project for the monumental gate of Munich, in Königsplatz.

The plan of Friedrich Von Gärtner and the barracks of Vasilissis Sofias street in 1836

Friedrich Von Gärtner is the reviser of the plan of Leo von Klenze. He maintains the general form of the plan of the city, its density and the character of its streets and squares, but he decides to move the government complex to the east part of the city, on the eastern vertex of the triangle of the plan, near to the foothills of Lycabettos. The previous position of Klenze’s plan was judged unhealthy because of its proximity to the marshy river Kifissos (Biris 1996). He drafts a plan without the squares of the different urban centres, but with only one axis ranging from the royal palace to the round square on the northern vertex of the triangular plan, where are situated the most important public buildings of the university, the academy and the library.

With the construction of the royal palace (1836-1842) begins also the construction of the first military barracks, putting an end in this way to the temporary accommodation of the army, with the settlement of two military complexes along Vasilissis Sofias street, in an obvious relationship with the royal palace (Figure 4). The plan of Gärtner is very essential and because of the limited resources there isn't any intention of designing a great number of public buildings and consequently there isn't any intention of a well-planned military complex around the royal palace. It was thought only a large area at the foothills of Lycabettos as military site, well-connected with the royal palace through the axis of Vasilissis Sofias avenue.

Figure 4. Analysis of the relation between the first military buildings and the royal palace.

Vasilissis Sofias is the contemporary street of an ancient road towards the suburbs of Mesogea, but finished to be almost a country road before the plan of Gärtner. With the military settlements along its axis, the street became in the course of time one of the most important avenues of the modern city.

During the fifties it wasn't necessary anymore for the Greek Army to be in possess of all the military buildings in the area and for this reason many of them returned to the municipality of Athens.

Unfortunately, the municipality decided not to re-use all these important buildings but to demolish them, so as to create space for the construction of a number of other public buildings such as important museums, the National Gallery, the war museum, the American Embassy and the Auditorium, losing in this way a significant part of the architectural heritage of the city.

The barracks of the cavalry in Pedion Areos 1860

The barracks for the cavalry of 1860 in Pedio Areos are the first to be built outside the city and away from the royal palace and it is the first to abolish the established relation between the two main urban elements, the centre of the government and the military centre.

The complex of the military buildings is located in the immediate vicinity, in a distance of about 200 metres of Patission avenue, the important urban axis that connects the suburbs of Patissia and Kipseli with the centre of the city (Figure 5). At the period of its construction the whole region around was a rural area. For this reason the only structures with which it has to be measured were the monasteries and few rural villas and it could be said that its settlement was an attempt of urbanization. From the plans is possible to understand that it was a complex of buildings of interesting volumes and with facades of high civil importance. The succession of architectural elements, such as tree-lined streets, the square in front of the entrance, the facade, the courtyard with its internal parade ground creates in this way a certain number of interesting urban spaces.

During the thirties the barracks was abandoned and in 1944 after a fire it was decided the demolition of the buildings.

Figure 5. Scheme of the barracks in Pedion Areos.

The Army Officers School in Pedion Areos by Ernst Ziller in 1900

Pedion Areos is a place of great symbolic value for the modern history of Athens; it was a place for military exercises that later became one of the sites for the construction of military barracks and recently became a place of memory for the heroes of the Greek revolution of 1821. In 1860 there were built, as above mentioned, the barracks for the cavalry and from the 1900 until 1904 it was constructed the army officers school designed by Ernst Ziller.

The school was built on a dominant part of the place and with a rich architectural facade of high civil value, which at the same time is contradicted with its isolated position. It is difficult to see in this operation the construction of a temple; in fact it is easier to see an attempt of urbanization of this rural area (Figure 5). The buildings drawn from Ziller are positioned not so far from the other complex of the cavalry, but the two settlements not seem to take into consideration each other. The only common element appears their relation with the natural elements and with the physical features of the ground; both of them are adapted to the course of a little river situated to the north of the site. Ernst Ziller designs eleven buildings, all arranged around an exercise parade ground; the main building of the command, which is the principal building of the whole complex, the school building and other smaller buildings as dormitories for the soldiers.

The case of the Army Officers School is regarded as a successful example of reuse of military architecture in the contemporary city. In 1984 the Greek Army decides to keep only the command building and to return the rest of the complex to the municipality. The architectural complex is considered an asset of high importance and the municipality of Athens decides its maintenance and its transformation into a courthouse.

The part of the project regarding the reconnection of the area with the rest of the city is limited to the creation of a square in front of the main building, as a way to exalt its front, without considering the challenge of a project that aims to combine the different elements, that are present into the green area and to form in this way a harmonious whole. Moreover, it is very important the connection of these elements and of the entire green area with the city.

The military barracks in Goudi

When begins the construction of the barracks in the early 1900s, Goudi is still a rural area where even the road network is rare (Figure 6). In this large area, were constructed several military

complexes, in separate moments and with a different use. Around 1920 were transferred here also the royal stables from the centre of the city.

Figure 6. Scheme of the barracks in Goudi.

These isolated military settlements become not only factors of urbanization but at the same time they become the circumstance of the preservation of these areas and of their protection from the division of the ground in building lots and a subsequent dense housing development.

In 1977 it was decided by a decree-law the restitution of an area of 96 hectares and 40 buildings to the municipality that defined their reuse for cultural and sports activities. In the end, only 45 hectares are returned and what still misses is the institution with the law of the Metropolitan Park of Goudi (Polyzos, 2008).

In 2000 started the re-use of an area of about one hectare, consisting of four identical buildings, a parade ground and the green area in front of it. Two of the buildings house the National Glyptotheque, while the other two remain still abandoned. (Figure 7) The complex was inaugurated in 2004 with the occasion of the Olympic Games.

Figure 7. The entrance of the National Glyptotheque in Goudi.

Conclusions

After having examined the most significant cases of military architecture, it can be said that military buildings in the first plans of Athens were built close to the royal palace, maintaining

their relation with the rest of the city. The projects of the barracks are part of a general urban design, characterized by strong relationships between the various elements. While regarding the more recent examples, we notice a weakening of these ties and the construction of introvert and isolated buildings from the rest of the city. In short, the first thing that emerges from this analysis is the fact that the first projects of the barracks during the nineteenth century are strongly correlated with the plans of the city, urban elements and urban history.

Moreover, as it can be seen from the last two areas analyzed, the re-use of military areas of Athens from the eighties onwards have often had positive outcomes. A huge architectural heritage is preserved and is decided to reuse these buildings with new functions, with the arrangement of public institutions and with the creation of large open spaces.

Taking a look on the urban area of Athens it is easy to understand that a considerable number of the urban green areas consist of former military settlements that the army decided to return to the municipality. Although in cases the military buildings are demolished, such as the large complex along Vasilissis Sofias avenue, it was created a large number of urban spaces that have opened up new opportunities for the growth and the expansion of the city (Figure 8).

Figure 8. Analogies, differences, distance from the urban centre of the analyzed cases.

Abstract. *Urban form which is defined as the union of streets, plots and buildings, in the historical evaluation of the towns, also represents legal entities which imply tools for urban planners and designers to design, to transform or to conserve the sites. In this context, this study aims to recognize urban form as a product of property relations and investigate the morphological regions in the case of Istanbul's Historical Peninsula by constituting its discussion on basic concepts of M. R. G. Conzen's morphologic analyses of historical towns. The elaboration for the transformations of urban blocks between 19th century Ottoman period, early republican period of Turkey and historical persistence of the urban form up to today are analyzed in Beyazıt, Aksaray and Yenikapı regions in particular. Thus, it is observed that subsequent to the effects of modernization movement on urban form in Istanbul, large-scale physical interventions transformed urban blocks and contributed to changes in property patterns. The dependence between urban morphology and property relations is emphasized in terms of the development of urban form within historical process. Additionally, due to progressing projects in the peninsula, the danger of disidentification of the Historical Peninsula is indicated.*

Key Words: *Historical Peninsula, morphological regions, urban blocks, urban morphology, property relations.*

Introduction

Reproduction of urban space depends on the transformation of urban form in terms of property relations. When urban designers, planners and architects work on built environment, it should be managed by considering historical progress and the two folded influence between form and social activities. Particularly, in urban morphological studies, it should be practiced by getting to the root of the components of urban form. The morphology schools of British, Italian and French, having researchers with different backgrounds, observe the urban form for particular goals through particular methods. The British school of morphology focused on how urban space should be built and why, while the Italian school looks for the answer of how cities should be built. French school emphasizes on past design theories to find out what should be built and what has actually been built. However, as Moudon (1997) points out they all studied on urban form with consideration to historical processes and analyzing the main elements of the city; buildings, plots and streets. Larkham states the importance of recognizing urban form and its components as following: "Understanding the physical complexities of various scales, from individual buildings, plots, street-blocks, and the street patterns that make up the structure of towns helps us to understand the ways in which towns have grown and developed" (Larkham, 2005, p.22). Street, plot and building patterns constitute urban blocks based on their physical and territorial connections. The effects of streets to the plots, buildings and the whole block are also crucial for defining what urban block is. Therefore, urban blocks refer to public and private patterns through these relationships of street, plot and buildings as the components of an urban block (Baş, 2010). In this study, urban blocks with each of its components became the main

subject. Regarding this, transformation of the urban space is clarified through elaborating urban fabrics of three regions in the Historical Peninsula.

Günay (2006) explains that urban form production refers to the two and three dimensional combinations. In order to reorganize or design the parts which indicate identity of urban form, firstly property, as two dimensional, is a need for them to be reshaped or reserved. In this process, the form of private and public space of the city is settled. Therefore, the concept of development rights determines the three dimensional form through property reorganizations. As long as it creates the form and space of the cities, ownership structure and legal establishments like development rights influencing morphology of the urban spaces, indicates significant design problems for designers (Günay, 2006).

In regard to this perception of urban form components, examination of urban blocks from the maps within different resolutions and different historical periods as can be seen in Conzen's studies are recognized in order to clarify the connection between morphology and property relations.

Influence of property relations on urban morphology

The evolutions of the property concept and its enforcements have been changed according to the societies. However it can be seen that the meaning of property refers to particular objects from the definitions. Günay (1999) states that claiming the property only as some objects to own separates it from the main concept substantially. Many theorists construed the concept according to the basis of being private, common or public and a bundle of natural rights or legal enforcements of societies. Property rights are highly associated with the laws, the state, economy and culture. Usufruct, exclusivity and alienability which can be owned by solely one person or can be shared by counterparties are also the rights implicated in property. These rights bring along some permanent relations, which can be seen as the recognition of plots and building blocks surrounded by street patterns in urban space. Evolution of urban space as a product is determined through property relations. Macpherson (1978) explains property relations in the context of Marxian thought as outcomes of significant crisis in history beforehand such as transformations in regimes of countries, and following relationships between land ownership systems. Primarily production relations within economical basis bring property relations. Property relations, in which production and consumption activities maintain, generally influence the space. As well as being the main subjects of property, structures and lands constitute physical expression of urban space. Property relations contain *usus fructus* or *abusus* of space, occupations, possessions, dominations. They also explain the dualities like right or thing, absolute or relative, ownership and possession, private and public, corporeal or incorporeal, movable or immovable (Günay, 1999).

The political power or the state recognizes the property ownerships, therefore legal relations become determinant for organization of urban spaces (Günay, 1999).

Morphological explorations in the Historical Peninsula

Istanbul is the most crucial city in Turkey with regards to social, economical and demographical parameters which have been affecting the city since Byzantium period. With its long historical background, the changes in the morphological structure of Istanbul can provide us to understand what kind of relations among urban planning and urban design practices, socio-economical activities and politics have influence on urban form.

In this respect, Istanbul's Historical Peninsula is taken as the case area. The Historical Peninsula is surrounded by Bosphorus, the Golden Horn and the Sea of Marmara. Transformation of urban fabric in the Historical Peninsula is explored in detail through the cases of Beyazıt, Aksaray and Yenikapı as shown in Figure 1. Beyazıt and Aksaray regions, connected to Ordu

Street which constitutes the spine of the Historical Peninsula ever since Byzantium period. Yenikapı region, having its boundary with the sea, is located next to Aksaray region at the south part of the peninsula.

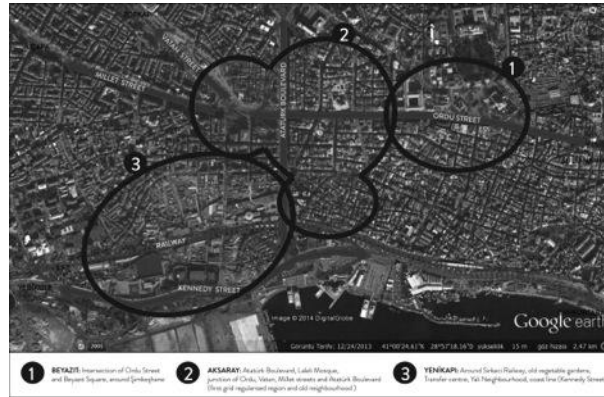

Figure 1. Focused case areas and important transportation axes which become deterministic for the study. 1st region Beyazıt, 2nd region Aksaray, 3rd region Yenikapı.

Beyazıt Square and surrounding

In Roman period (Figure 2), place of Beyazıt Square was Forum of Theodosius which was located on the space between Beyazıt Mosque and madrasah of today. It had a triumphal column in the middle like other Roman forums and it was connected to Mese. There was a triumphal arch which was erected on the west side of the Forum. Also, today's area of Istanbul University (faculty of letters and sciences) had been at the place of three Basilicas of Byzantium. Around the forum, civic buildings like churches were built (Kuban, 1996).

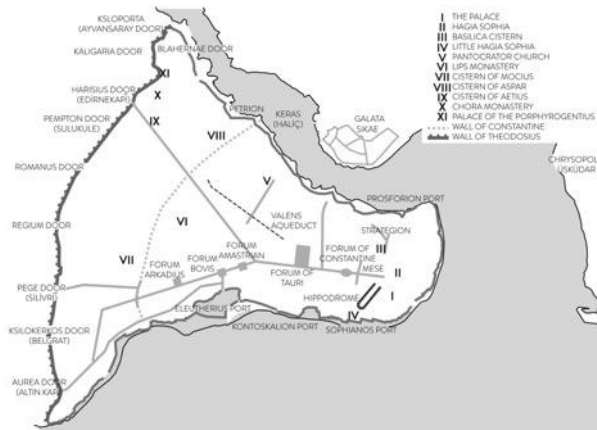

Figure 2. The Historical Peninsula at the Byzantium Empire period.

As Istanbul was conquered by Ottomans in 1453, Old Palace was built at the north side of the forum, where is the highest point of Beyazıt. Mint of Ottoman (Şimkeşhane), bazaar areas and Grandbazaar were formed at this period. In the 1500s Beyazıt Mosque and *külliye* (Islamic social complex) was constructed and the square took a new shape and it became the centre of Istanbul. In the 1800s the Mosque integrated to Beyazıt Square. In 19th century, the square was used as bazaar/exhibition area (Kuban, 1998).

In early republican period of Turkey, Beyazıt Square was designed and planned many times. Between 1923- 1924, a fountain pool in round shape was placed in the middle of the square and tramway line entwined around the pool (Kuban, 1998). Later, motor vehicles dominated the area. In 1933, the Old Palace building was given to Istanbul University. With the plan of Prost in 1937-1938, traffic flow was removed from Beyazıt Square and it began to serve as a public square again. In the beginning of the 1940s, the faculty of letters and sciences of Istanbul University was built. The building became a new morphotype with its huge size and architectural style in the urban fabric.

The significant changes in these areas were seen in mid 1950s. In the years of 1956-1957, known as Menderes period in Turkey, Divanyolu (Ordu Street) was expanded from 9,5m to 30m. That development in the spine of the Historical Peninsula brought the destruction of many historical buildings like Şimkeşhane and Hasan Paşa inns as well as several urban blocks (Kuban, 1998). Moreover, with the expansion of Ordu Street, Beyazıt Mosque, the bath, and some other commerce buildings began to stay in upper level whereas Ordu Street was developed in lower level. After that, new commerce and business buildings began to build up in the area. In the 1960s, several projects for Beyazıt Square were added to the agenda. Especially after 1980, urban design competitions were organized for the square. Transformations in urban fabric of Beyazıt can be observed from Figure 3.

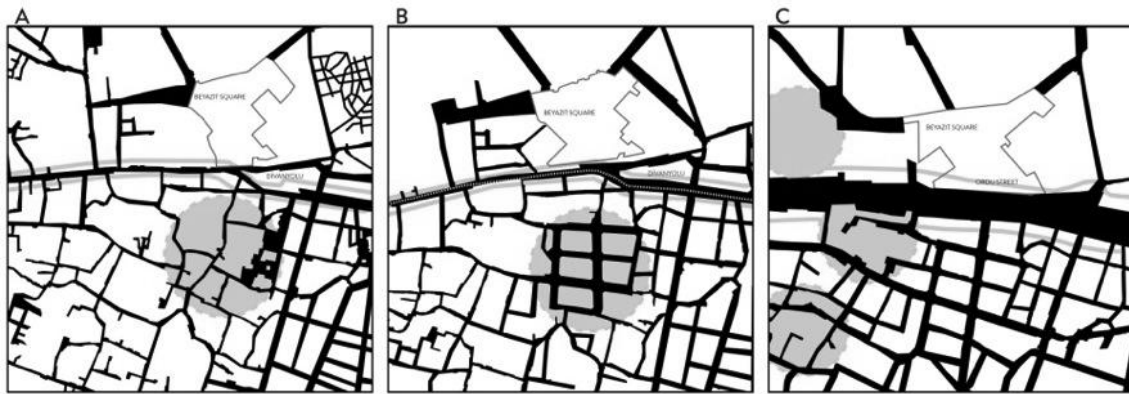

Figure 3. Changed regions marked in street pattern maps of all periods in Beyazıt. A) based on map of 1875 B) based on map of 1935 C) based on map of 2011.

Widening Ordu Street and destruction of historical buildings

In 1470s, old Mint of Ottoman was built in the place of Şimkeşhane. Educational facilities and shops were added to Şimkeşhane in 1700s. Since the mint was moved to Topkapı Palace in those years, Şimkeşhane had begun to be used as an inn. Next to Şimkeşhane, Hasan Paşa Inn was constructed in 1740. Şimkeşhane was abandoned after the fire in 1826, although it was repaired in 1867. During the Republic period, as well as some other buildings and building blocks, the north parts of these buildings were demolished (see Figure 4) in order to expand the road connecting Beyazıt-Aksaray; Ordu Street, in the years of 1957-1958 (Gül, 2012). This caused a significant change in the buildings' physical structure. The courtyard of the buildings began to face Ordu Street and Beyazıt Square.

In the mid-1960s, it was decided that the rest of Şimkeşhane building was to be used as a public library, so its restoration was finished in 1976. Archaeological findings of Forum Tauri from Byzantium period were exhibited in front of the building. Since 1981, the building has been serving as public library of the city of Istanbul, still having an open green space with the archaeological exhibition.

Figure 4. Building blocks destroyed in widening of Ordu Street, based on Pervititch map of Beyazit.

Aksaray: fires, regulations, boulevards

Aksaray region was located at the east end of the Mese in Byzantium period. It was near Forum Bovis and today's Aksaray Street was around Amastrian region. Aksaray was an important trade centre and transportation node since it was on the most primary road of the town and it was quite close to Theodosius Port (Kuban, 1998).

After Ottomans settled the city, this region lost its commercial utilization. Aksaray was populated by the people coming from the city of Aksaray of Anatolia. Thus, the region was named as Aksaray and it was filled with residential buildings in 17th century. Aksaray was one of the most important regions during Ottoman period because of being at the junction of main transportation axis of the town and the huge green areas. Kuban (1998) identifies Aksaray as a meeting place for Muslim and Christian communities around the region. He also claims that Murad Paşa Külliyesi, Pertevniyal Valide Sultan Mosque and Laleli Mosque are the most significant buildings which represent Ottoman identity in Aksaray (Kuban, 1998). This region serves as a model for very urban fabric change in the Historical Peninsula of Ottoman's. In 1856, more than 650 buildings were burned and destroyed in the fire of Aksaray (Çelik, 1993). With the code of 1856⁴⁴, the expropriations were brought to the agenda in case of the regulations such as street widening. Therewith, based on new urban policy of Tanzimat, Mustafa Reşit Paşa, who especially believed in regulation of urban blocks with geometric orders after the fire near Beyazıt Mosque in 1826, tasked Italian engineer Luigi Storari in order to regulating post-fire Aksaray (Pinon, 1998).

Storari reorganized the organic urban fabric of Aksaray as a grid pattern (see Figure 5.B) as it was expected from the authorities supporting modern changes in the urban pattern. Storari's work grounded on existing substantial axes in the direction of north-south (Unkapanı-Yenikapı direction) and east-west (Aksaray Street). He endeavored to widen and straighten the streets in those directions. Determining the main artery of the region as Aksaray, he expanded the width of the street to 9.5 meters. Since Storari gave the importance to those axes, he strengthened them with 7.6 m and 6 m wide parallel and intersecting roads (Çelik, 1993). Pinon states that in order to comforting existing narrow roads, Storari cut the corners of the urban block boundaries at the important intersections by describing them as; "The four cut planes define peculiar lozenge-shaped crossroads" (Pinon, 1998). Indeed, the grid plan of Storari was not regularized

with perfect angles and great shaped urban blocks, instead, size of the new urban blocks were similar to pre-existing ones. Although there was not a major change in building sizes, through the cut planes and removing cul-de-sac forms of organic urban fabrics as a result of grid system, some buildings got smaller (Çelik, 1993).

The fires that ended up with the destruction of neighborhoods leded the authorities to provide Street Construction Code in 1863 that was aimed street regularizations based on widening, straightening or leveling. Considering pre-existing street networks, it was decided to prepare new plans. While expropriations were practiced for street widening in that process, allotment of lots for property owners were implemented. Pinon states that: "Aside from indicating that they should be proportional to the original parcels, no official requirements for the new designs are mentioned. But neither is design left to private discretion, since public authority controls the overall organization and allocation" (Pinon, 1998, p. 56). In 1882, including regulations about street widening and opening, planning fireplace maps, the heights of the buildings and land ownership, the first construction law of Ottoman Empire (Ebniye Kanunu) was introduced (Tekeli, 2011). As seen in the case of Aksaray, other urban fabrics destroyed in fires begin to be formed in grid systems based on this law.

Aksaray was regularized for the second time after the 1911 fire which brought along the design of the largest urban block of the peninsula. Andre Auric who took the helm of Infrastructure Department of Municipality of Istanbul in 1910, emphasized on need of large boulevards minimum of 32.5 meters in order to improve conditions of health, security and infrastructure services. He also supported the idea of transforming military properties (like barracks) to park, public square and garden areas in the city. In Auric's proposed street network plan for Istanbul, Aksaray region had a great significance (see Figure 5.C). A square, which was located at the intersection of the roads coming from Beyazıt and Theodosian doors, was proposed by him. In Auric's plan, in addition to aesthetics, infrastructure service and open space systems were tried to be developed through geometrical urban block regulations (Gül, 2012). Two wide diagonal streets interrupted the urban blocks entailed truncations principally as Pinon (1998) claims. Streets were organized in hierarchical order. Even though urban blocks were generally defined in same dimensions, in Aksaray example expand of urban blocks varied between minimum 20 to 30 meters, with a maximum 30 to 70 metres (Pinon, 1998). Gül (2012) states that lately the proposed boulevard axes between Aksaray and Yenikapı became one of the important traffic roads of modern Istanbul. Those urban fabric regulations with widened roads in grid layouts for modernizing also became the roots of subsequent changes in urban form which has been mostly seen as expanding the roads.

The first apartments of the Republican period were constructed in the urban blocks which were formed as a result of the orthogonal street system. Aksaray and especially Laleli region, became the neighborhood of mid-classes of the society (Kuban, 1998).

In the early Republican period, in 1937, when Henry Prost charged to make the plan of Istanbul, based on Haussmannian idea of urban planning, he focused on transportation network of the city by considering population rise and automobile usage (Tekeli, 2011). In Prost's plan, the part of Atatürk Boulevard between Aksaray and Yenikapı was already built according to Auric's plan, and created the spine of the traffic plan. The boulevard coming from Yenikapı and reaching the Golden Horn connected to Beyoğlu region through Atatürk Bridge. Gül (2012) explains that, despite having the extensions of Atatürk Boulevard in cadastral maps of Pervititch in 1936, it was not exactly practiced till Prost's plan due to the economic inadequacy of that time. Width of Atatürk Boulevard increased to 50 meters and it was integrated with several squares from different parts of it.

In the middle of 1950s, urban planning approach of was predicated on the connection of commercial and administrative regions via large roads. Regarding the developments on Ordu Street from the east side and Millet and Vatan streets from the west side with Atatürk Boulevard in north-south direction, Aksaray became the most significant region by being at the intersection of the most important transportation structure of the Historical Peninsula (Gül, 2012). In order to provide construction of expanded roads, a great number of destruction executed in the region

as in other urban regions of Istanbul. Those construction activities also caused the decrease of resident population in the region and the deformations on the urban form. Several historical buildings were destroyed.

New connections and highways brought rising population along. Therefore, as a major point of the peninsula, Aksaray began to be shaped with apartments with commercial activities in ground floors after the 1960s. At the end of the 1960s and the beginning of the 1970s, with the construction of viaduct in Aksaray, at the junction of Atatürk Boulevard and the streets of Vatan and Millet destroyed Aksaray Square and a complex motorway network was built in the middle of the Historical Peninsula. Also Valide Sultan Mosque fell behind the raised roads and lost its spatial effect in time.

Kuban (1998) claims that historical core of Aksaray was destroyed, because transportation systems was planned by highway engineers and urban conservation concept and consciousness did not developed in those years. Widening of Ordu Street caused the expansion of commercial areas to Laleli region. After the 1970s, residential areas disappeared and Laleli was transformed to a region of commerce and tourism. Old apartments are turned into mid-class hotels and commercial buildings (Kuban, 1998). In the 1990s, after bus terminal of Istanbul moved to Topkapı, especially in Aksaray-Laleli region, a major development of hotel management was seen. Thus, as a sub region of business, that region has continued its commercial utilization.

Figure 5. Changed regions marked in street pattern maps of all periods in Aksaray. A) based on map of 1847 B) based on map of 1875 C) based on map of 1935 D) based on map of 2011.

From the port to the transportation node: Yenikapı

During the Byzantium period, Yenikapı was at the region of Theodosius Port which was the major port of the city. Port of Theodosius was settled in the mouth of Lykos River. It was the trade point with Egypt's wheat carrying ships. As well as residential areas and bakeries, it is said that a few dockyards were existed in that period (Kuban, 1996).

After Ottoman's conquest of Istanbul, the shrinking port area - due to the deposition of soils coming from Lykos River - began to be used as dockland area in 1500s. As the port area became smaller in the 1700s, relationship between the port and the sea began to fall. Hence, the character of the region came to a change. The area remained inside of the city walls was called

as Küçük Lagna Bostanı (small Lagna garden), as for the areas outside of the city walls called as Büyük Lagna Bostanı (big Lagna garden). Yenikapı remained as vegetable garden area until 19th century. The only neighborhood, which is called Yalı neighborhood today, in Yenikapı was built by a group of Armenians in 1760s, after the debris of construction of Laleli Mosque was filled the area and stone barriers against the waves from Marmara sea were built. The location of Yalı neighborhood is at the intersection of Atatürk Boulevard and the coast road.

In 1846, the Armenian Church Surp Tateos Partoğomeos was built in the neighborhood. Urban fabric of the region was composed of rectangle urban blocks in grid layout with attached wooden or masonry buildings having a bay window. According to Prost's plan, in the Republican period, Yenikapı train station would have been an international one, bringing along a modern development on the Yenikapı port.

As seen in previous regions in the study, the most destructive changes in the history of Istanbul took place after the 1950s. In Yenikapı, with the construction of coast road; Kennedy Street reaching from Sirkeci to Florya, the shore line was filled. Therefore, the connection between Yalı neighborhood and the sea was broke off.

After 1980s, large-scale projects - which have resulted in various transformations and problems in urban form and urban life - began to come up because of the planning goals of Istanbul in the global scale. In Figure 6, development of coastline of Yenikapı can be seen based on illustrated maps.

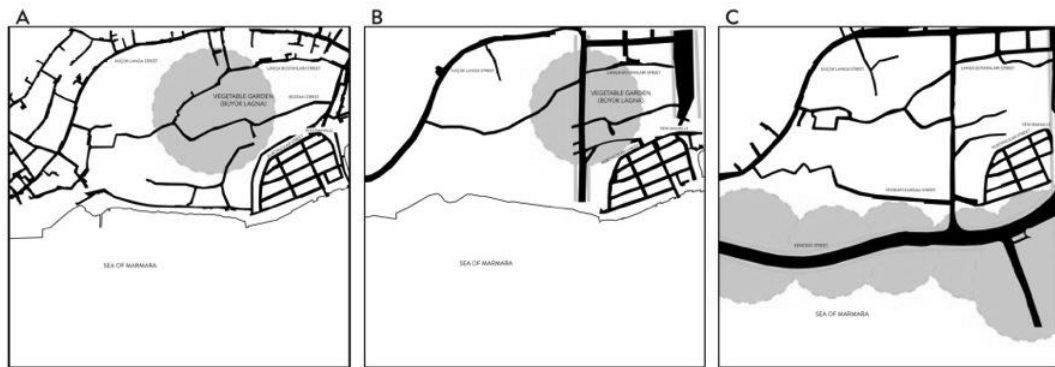

Figure 6. Changed regions marked in street pattern maps of all periods in Beyazıt. A) based on map of 1875 B) based on map of 1935 C) based on map of 2011.

Although in the 1990s, conservation decisions were constituted in the historical towns in Turkey particularly, the rising population of metropolis of Istanbul and its urban problems required new transportation solutions. Today, in order to solve the transportation problems of the whole city, Yenikapı is determined as the biggest transfer centre of Europe being at the Integration of subway of Taksim-Yenikapı, subway of Aksaray-Airport, IDO and Marmaray as the biggest transfer centre of Europe, and an exhibition area is proposed for archaeological findings that came to light through excavations of the projects. Moreover, a new (filled) square is constructed on the Marmara Sea. The square is coming from IDO port to Samatya Training Research Hospital, as a 715000 m² filled meeting, demonstration, exhibition, and concert or expo area, approximate for 1 million people (Figure 7).

These projects incompatible with the identity of the peninsula have been influencing the urban form of the Historical Peninsula as well as Yenikapı region. As a result of being the major transportation node of Istanbul, the movement of the whole city will be the carried by the Historical Peninsula. With the new filled square project, from and silhouette of the Historical Peninsula was largely changed by a man-made for the first time. Yenikapı may be excluded from the world heritage site of UNESCO. Also, the lands of the peninsula will become open to change as a result of property relations. Thus, conservation of the peninsula will become

impossible and a significant transformation in the urban fabrics of the Historical Peninsula becomes unavoidable.

Figure 7. Yenikapı Square as fill area changes the form of the Historical Peninsula, 2014 Google Earth image.

As a consequence of these three regions of the Historical Peninsula elaborated above are examined regarding transformations of building blocks according to the maps of 1935 and 2011, in order to see the effect of the property relations on building fabrics.

Practice of morphological regionalization

The morphological approach of Conzen mainly centered on historical development of town plans. Whitehand asserts that: “In this way the landscape becomes an ‘objectivation of the

spirit' of a society in a particular locale" (Whitehand, 2009, p.8). Having same identical features in terms of evaluation of urban forms, morphological regions can be founded in town plans, building fabrics and land and building utilizations (Conzen, 2004). This analysis method generally involves four hierarchical morphological regions which are grouped by Conzen; the old town as a whole is described as first order, town quarters represent second orders whereas street, neighborhood or precinctual units are third order, and smallest building groups of a dominant period or morphotypes are fourth order. In this respect, the number of hierarchical levels can be discussed according to the study area. Especially in historical towns, number of orders can be increase or decrease considering structural changes or mergence in the towns (Conzen, 2004). Recognizing this classification of Conzen, the method is practiced on the analysis of land ownership patterns and town plan analyses of the case study areas.

Town plan analysis

Conzen defined the main determinants of urban landscape in three parts: the town plan (or ground plan), building fabric (the 3-dimensional form) and land and building utilization. This tripartite division of urban landscape contains the conceptualizations for examining the process of urban development. He asserted that the persistence of the townscape determinants differentiated in time. With the strongest persistence, town plan constitutes from urban block components: street networks, building blocks and plot patterns (Conzen, 1960). It indicates the analysis of areas delimited according to their ground plan. Each town plan analysis is created in order to draw hierarchical morphological orders. Since the first order shows the old town as a whole and the second orders show main plan units, in our study scale, the third and fourth regions are emphasized as well as predetermined second orders. In addition to this, first and second degree conservation areas are indicated with morphological regions.

The Historical Peninsula of Istanbul as a whole constitutes the first order because of its persistence as a multi-level urban fabric beginning from Byzantium period till today inside of the city walls. Primarily walls of Theodosius are taken as the region boundary. In second phase, according to urban development directions, urban fabric configurations, major structural divisions, historical process and the regions within definite identities are considered. Consequently, 15 regions are founded inside of the first order whereas 4 other second order regions are identified outside of the city walls where filled coast areas are, as can be seen from Figure 9.

Figure 9. Morphological reigons of the Historical Peninsula (First and second orders only illustrated).

A base map in scale 1:5000 is used for settling the first draft of the first and second regions. Subsequently, several maps of different periods are superposed, in the same scale in order to determine the technicality of the orders. The map showing significant urban development in Byzantium, Kauffer map of 1789, 1914 map that was drawn in scale 1:25000 for showing urban

blocks, the general street network map of the years between 1925-1950, and Google earth maps of 2005 and 2014 years are used as base maps.

Focused study areas in this study are determined as Beyazıt, Aksaray and Yenikapı regions as stated before. In this way, third and fourth orders of these areas' morphological regions are analyzed in a closer scale.

In this analysis, the insurance maps of Pervititch that were created in 1935 and last base map (2011) of the Historical Peninsula that is obtained from the municipality are superposed in order to observe urban block changes from the early Republican period to early years of 21st century.

Beyazıt: Beyazıt Square next to Ordu Street and other linked urban blocks are analyzed by emphasizing the changes in urban block components from 1935 to 2011 (see Figure 10.A). Buildings built before 1935 and buildings built between 1935 and 2011 are dissociated. Streets are classified based on building before 1935, between 1935 and 2011 and also physical changes between reference periods. General land use of buildings according to 2011's data is also defined. As distinct from Conzen's analysis, lost structures which have historical significance (based on Historical Peninsula conservation plan analysis, 2011) are indicated.

According to the map, it is seen that especially built environment around Beyazıt Square, at the north side of Ordu Street is constructed before 1935. On the other hand, south side of Ordu Street is mainly constructed after 1935. Moreover, the most significant change in urban pattern is seen at Ordu Street itself. Expansion of the street created new borders of neighbourhoods beside it.

As a result of this analysis, morphological regions in Beyazıt are defined (see Figure 10.B). Considering proposed orders for Historical Peninsula, second, third and fourth orders of morphological regions are determined. Since second orders represents urban quarter with main plan units, it only seen as passing through Ordu Street by dividing study area into two. Within third order regions, urban blocks are grouped according to historical persistence or change. Also, layouts of urban blocks and land uses are considered. Therefore, within the study area boundary, approximately 16 different regions of third order are founded. Inside of these regions, some specialized buildings or building blocks are referred to morphotypes which indicate fourth order. Building block size, grand physical changes or any significant differentiations among other urban blocks became determiner of fourth order as can be seen from the map. In this sense, faculties of Istanbul University are bounded based on its huge block size, as well as Şimkeşhane and Hasan Paşa inns are bounded because of significant change in blocks.

Aksaray: Town plan analysis of Aksaray (see Figure 11.A) also indicates urban block components which are built before 1935 and after 1935. According to the analysis, high density of the buildings built before 1935 are mostly gathered around Laleli Mosque and south part of the area. This region is the end of Ordu Street. From this point, the spine of the peninsula goes into division as Vatan and Millet streets. The most remarkable change between 1935 and 2011 is founded as the junction and viaducts in the area. As well as the street is expanded, Atatürk Boulevard, which extends in north-south axes, is connected to other streets with the roads in different layers. Construction of Atatürk Boulevard affected urban blocks, especially at the north side of the peninsula, and it is concluded with many urban block destructions. Except for that, general layout of the urban pattern is constituted before 1935 as can be seen from the analysis.

In morphological region analysis (see Figure 11.B), a second order line is seen as splitting Aksaray from Yenikapı region. Building blocks around Laleli Mosque, Valide Sultan Mosque at the west side of the map and the old neighbourhood at the north side are taken as third order regions as well as urban blocks in grid system or specific areas with a dominated land use. In the fourth order, old specific structures in third orders and great buildings are considered. Also, some archaeological structures such as Myralion church and its old forum area form Byzantium are taken as morphotypes.

Figure 10. Beyazıt. A) Town plan analysis B) Morphological regions based on town plan.

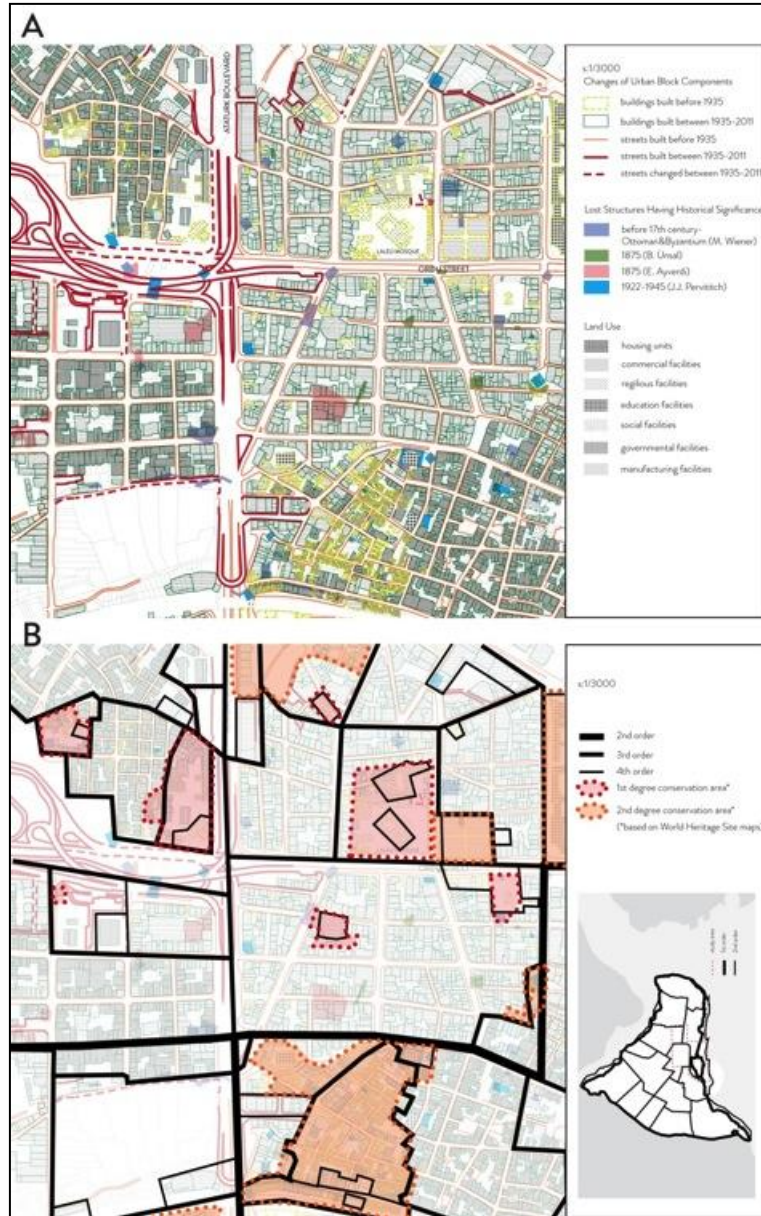

Figure 11. Aksaray. A) Town plan analysis B) Morphological regions based on town plan.

Yenikapı: In Yenikapı region, town plan analysis (see Figure 12.A) indicates that buildings built before 1935 are mostly founded at the south side of the map, in Yalı neighborhood. As a quarter with housing units, street network is also built before 1935 as can be seen from the analysis. Conspicuously, the coast side and the road system on it are constructed between 1935 and 2011. The rest of the buildings and roads occur as the structures built after 1935. In this map, based on Wiener's map, the walls of the Historical Peninsula are especially taken as historical lost structures.

In morphological analysis of Yenikapı's town plan (see Figure 12.B), principally walls are taken as the borders of morphological regions. These also represent the first order of the Historical Peninsula by being the main boundaries of the old town, as stated before. Subsequently, urban fabric in Yalı neighborhood, coast side, and empty areas (without settlements) constitute third order regions. Intersected conservation area on Yalı region is also founded in this third order region. Isolated buildings in empty regions are taken as fourth orders.

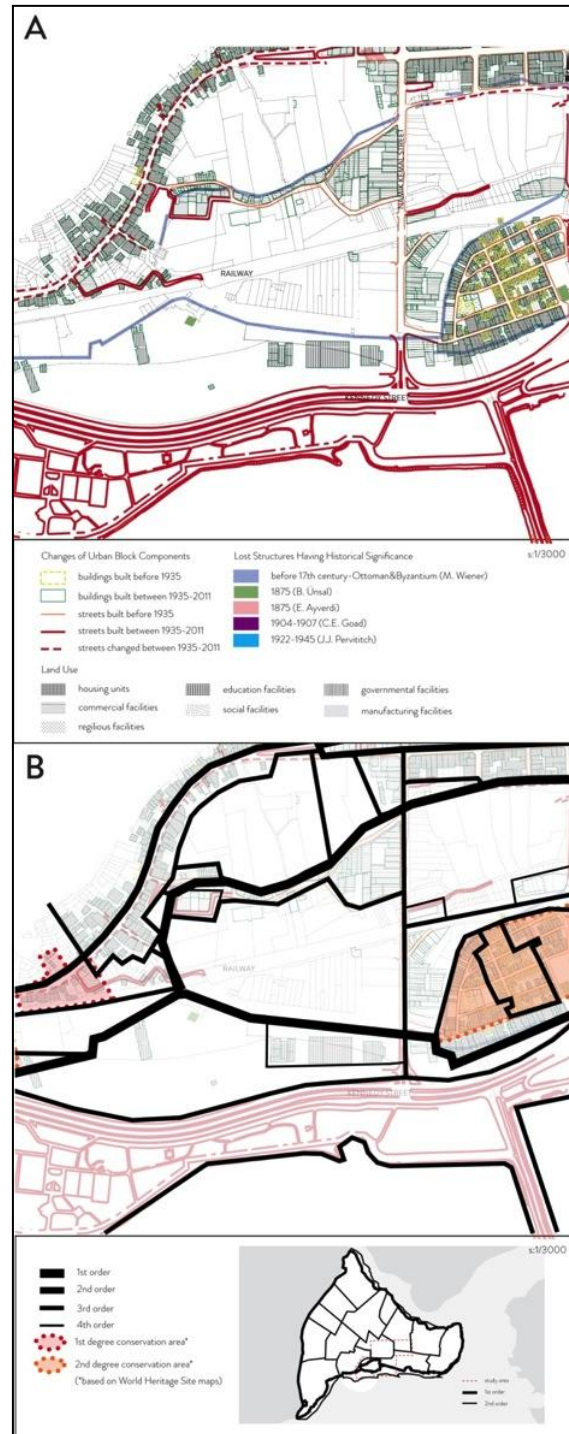

Figure 12. Yenikapı. A) Town plan analysis B) Morphological regions based on town plan.

Ownership patterns

Streets, buildings and plots require the examination in terms of property relations. Hence, the ownership pattern of the study areas is analyzed. Public, common, private, private foundation and foundation management classifications are determined and the patterns are created. As can be seen from the following maps; a great majority of the study areas contain private ownership patterns. Around Beyazıt Square, foundation and public lands can be seen. In Aksaray, except

for religious facility areas with foundation ownership and common parcels at the Yenikapı region, dominance of private ownership can be seen again. As the base of this study, land ownership patterns are considered as another complex to understand with morphological regions. The regions are determined based on dominance of an ownership type and illustrated as third and fourth orders since the ownership's of the lands has the direct effect on the formation of urban blocks (See Figure 13 and Figure 14).

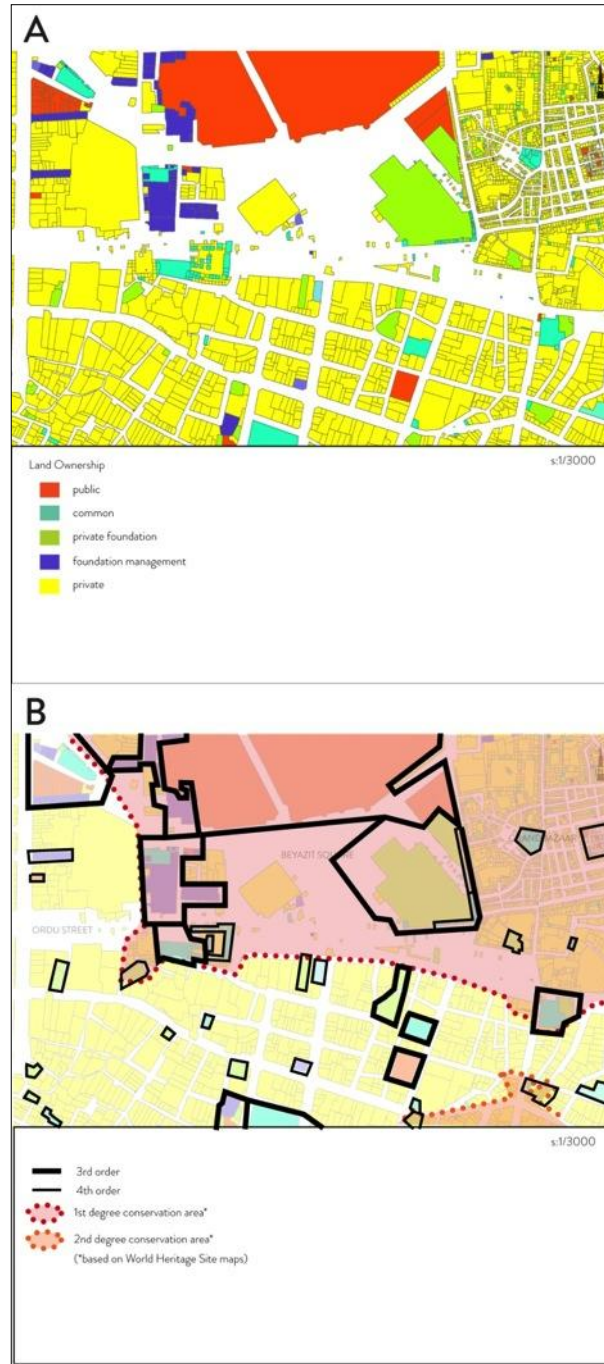

Figure 13. Beyazıt. A) Land ownership analysis B) Morphological regions based on land ownership.

Figure 14. Aksaray and Yenikapı. A) Land ownership analysis B) Morphological regions based on land ownership.

Conclusion

The connection between property relations and the morphological transformations based on form, time and resolution of different components is revealed through the research of urban/form changes according to definite planning approaches and political grounds in the study areas of Beyazıt, Aksaray and Yenikapı within historical process.

The Historical Peninsula's organic urban fabric, which constituted through Islamic politics with privacy concept and perceptivity of no private property, came to change through grid urban

block systems which were practiced in the modernization period of the 19th century. The configurational changes began to be seen with the destructions of great fires, legal interferences and regulations by providing property relations.

After 1950s, as planning policies of the government formed according to the changing economical system and lifestyles, construction of large street systems caused major destructions in old urban fabrics. During those periods, several characteristic units of the Historical Peninsula were demolished, and with the construction codes, expropriations were executed in the urban blocks which indicated complication for widening and opening new roads. With the rising population of Istanbul, destructions in the Historical Peninsula are tried to be prevented by conservation plans. However, conservation and restoration studies fell short. Besides, the form and character of the peninsula was damaged due to the wrong conservation and restoration practices of local administrations, renewal projects and coast filling projects.

In the cases of Aksaray, Beyazıt and Yenikapı, even though they are all the parts of the whole old town, counts of identified morphological regions based on town plan and land ownership analyses (showing same or different features) are tabulated (Table 1) as following:

Table 1. Number of morphological regions in the case areas of Beyazıt, Aksaray and Yenikapı.

Study Areas	Morphological regions of town plan analyzes	Morphological regions of land ownership pattern
Beyazıt	second order: 2 -partly third order: 16 regions fourth order: 9 regions	third order: 14 regions fourth order: 23 regions
Aksaray	second order: 3 -partly third order: 20 regions fourth order: 19 regions	third order: 29 regions fourth order: 44 regions
Yenikapı	second order: 2 -partly third order: 17 regions fourth order: 4 regions	third order: 14 regions fourth order: 13 regions

As a result of the difference in the areas of each study cases, in the morphological regions of town plan analyzes, the areas contains the delimitation lines of second order regions, which are determined within a larger scale in the whole Historical Peninsula. Therefore, at least 2 second order regions can be seen partly from the focused case areas and indicate major plan units of the old town. Especially in the case of Aksaray, identified regions seem higher than other study areas. Yet, third order regionalization gives approximately the same results. This can be seen in morphological regions of town plan analyzes of the areas around 20 regions; which indicate 20 character areas. For example, in the case of Beyazıt, 4 of the 16 morphological regions based on the town plan are showing the same character features while the others require distinct considerations. In Aksaray, 20 character areas and 6 of the regions, which represent built environment formed after 1935 with commercial utilization, can be discussed as reflecting character areas with the same identity; whereas the regions that are illustrated for Yenikapı indicate varied character areas. As well as the town plan, in the results of land ownership analysis, the fourth order regions are the evidence that in the studied parts of the Historical Peninsula, there are numerous morphotypes and building fabrics which can be the sign of complexity of the town or oncoming changes for some areas.

The complexity of the Historical Peninsula, indeed, requires a more detailed research in terms of determining morphological regions. Regionalization can be discussed by different participants in a joint study. Through this method, variety of character areas in a historical town can be ascertained. Although these regions can vary according to the planners or designers, similar regions can be recognized in general terms.

In order to prohibit the process of the system which makes the conservation of the old towns a tool for new identity formation, legal enforcements showing its spatial outcomes within property relations in detail of urban fabric must be built in a serviceable way, considering the identity of the historical towns from morphological structure to the socio-political stratifications. Thus, conservation studies in the historical towns should be managed in urban block detail by considering property relations subject to urban planning and design policies, and morphological regions based on a series of morphological analyses.

The transformation of the urban block in the European City

Maria Oikonomou

Department of Urban Planning and Regional Development, School of Architecture, Aristotle
University of Thessaloniki, 54124 Thessaloniki- GREECE
E-mail: moikono@arch.auth.gr

Abstract. *The research focuses mainly on the European cities' urban form and social characteristics by analyzing the element of the urban block in five historical periods. The aim is not to analyze the whole history, but to focus on specific periods and case studies that show the metamorphosis of the urban block. European cities are diverse in several scales but meanwhile they are linked in a common urban development. By studying examples from the Greek Polis, where the urban blocks are created by organized city planning focused on the grid, to the urban block of the medieval city, where different built structures can be seen, to the compact blocks of the industrial Berlin, to the large blocks of Transvaalbuurt in Amsterdam, where the traditional urban block opens up as well as Le Corbusier's modern city and the refusal to the traditional closed block, the reader will be able to understand the significant vital role of the urban block in the urban tissue. These case studies are examined, analyzed and, in the end, illustrated in diagrams based on indicators that show spatial and social characteristics of the blocks. Thus, one can observe urban transformations and social changes of the European cities always in comparison with the historical framework.*

Key Words: urban block, European cities, urban transformation, urban form.

The urban block as one interconnected system of social and spatial relationships

Plots - as the two dimensional space - and buildings - as separate individual component parts - fit together and create a three dimensional space; the urban block. Groups of urban blocks, surrounded by streets or public space, create the urban layout. On the other side, what makes the urban block special is its social-cultural aspect. What is important to realize is that the term 'urban' instantly refers to urbanity, to city and not to rural areas, to specialized ways of production and services, to the urban way of life. Meanwhile 'block' refers to the utilized form, which is perceived rather as a certain three dimensional shape. Given these points the combination of 'urban' and 'block' is associated to socio-economical as well as morphological parameters, defining what the 'urban block' is and what it is not. After all being a part of the city characterizes the distinctive nature of the urban block. These socio-economic features are the communication language between people and the built environment. Overall, that exceptional attribute gives to the urban block its social character.

Manuel Castells in his book *The City and the Grassroots: A Cross-Cultural Theory of Urban Social Movements* examines the city as a social output and how history relates to a socio-cultural context (see Castells, 1983). What is important to stress in this point is his theory concerning the consistent relationship between spatial and social aspects of urbanity. "Urban is the social meaning assigned to a particular spatial form by a historically defined society." (Castells, 1983:302) Within this thesis Castells achieved to express the complexity of relationships in cities. The same features can be found in relation to urban block; it is an element which creates relationships between the user and the built environment.

On the basis of these considerations, a contemporary definition of the urban block is proposed; it can be defined as one interconnected system of social and spatial relationships.

Typologies of european cities and case studies

When people think about european cities, they mostly have in mind cities in Germany, Italy or Spain, due to the fact that in these countries, the original historical city nucleus (often planned during medieval years) still exist in their initial urban form. For this reason, it is essential to point out that this paper attempts to prove that european cities are not only those who were built during the medieval years.

The special characteristic which connects all of the european cities together is the historically defined culture related in an inter-mutual european identity. Another issue is that they are linked in a common urban development, even if they have been effected in different ways, time frames and circumstances. Nevertheless, european cities are diverse in several scales; geographical, national, institutional, economical, etc. This diversity is also translated to the urban morphology but to the social character of the cities as well.

A brief review will be followed for each historical period respectively. Next, the case studies are examined, analyzed and in the end illustrated in diagrams based on the four layers of the urban block; the street, the plot, the building/s and the open space. Meanwhile each layer consists of indicators (see table 1), which serve as parameters and focus points of the analysis. The case studies were chosen within four criteria; the examples chosen should have been built, next they should show typical and general rules of planning, they should also be highlights in history or last, they should have influenced the european city development. But all in all the examples are accepted as ideal models for each time frame and are already well documented in the relevant literature, which is the primary source for the investigation.

Last, to avoid any confusion, I need to clarify to the reader four important issues. First, when valuable information was missing or was vague, there was the necessity to estimate values based on different input parameters and assumptions in order to obtain a complete image. Secondly, when it was not possible to estimate, in the end no indication is illustrated. Next, all the examples are explained in relation to the specific timeframe of the analysis and not to their present state. Last, all the calculations, such as dimensions and coverage, are fairly accurate but not exact.

Table 1. The indicators of urban block in relation to the four layers and spatial and social characteristics

Layers	Spatial characteristics	Social characteristics
Streets	1. Layout	1. Main orientation/function (pedestrian, car, mixed, etc.)
	2. Orientation of the street network (north-south, east-west)	2. Accessibility/circulation (to housing, to commercial, etc.)
	3. Hierarchy of streets	3. Use (public space, transitions space, etc.)
	4. Dimensions	
	5. Greenery	
Plots	1. Dimensions	1. Land tenure distribution (private or mixed with public)
	2. Space distribution	
Building/s	1. Architectural principles (form, roof)	1. Users (social status, age/family status)
	2. Materials	2. Uses (housing, commercial, mixed, etc.)
	3. Orientation (north-south, east-west)	3. Time (who, when, for what?)
	4. Floors [FAR; calculated as the building's total floor area (Gross Floor Area, GFA) divided by the net size area of the plot]	4. Ownership vs. rent
Open space	1. Dimensions	1. Users (public, inhabitants)
	2. Density [The total open space in the urban block is measured as Open Area Coverage (OAC) and the total built area as Built Area Coverage (BAC)]	2. Activities (recreation, transition space, etc.)
	3. Greenery	3. Ownership (public, private)

Greek Polis

Each Greek Polis was independent and had its own rules and norms of governance. Only men had right to land tenure and each one owned the same size plot with the facsimile house as the others. They were also the only ones who participated in politics. Women were excluded from the society and slavery was a typical phenomenon of the time.

Hippodamus of Miletus was the most famous ancient urban planner and usually called as the “inventor of city planning”. The Hippodamian system of the orthogonal rastered layout was his invention and it is called after his name. He was responsible for planning the city Piraeus (now a municipality of Athens) and is claimed to have also designed Miletus and Rhodes, due to the similar orthogonal planning system.

Urban blocks in Greek Polis were settled in the private sector. The use of the orthogonal grid for housing (oikos – in greek οἶκος) was the easiest way to offer everyone the same area of land. Kevin Lynch observes: “Defense, order, and a rapid and equitable allocation of house site and access seem to be the principal motives.” (Lynch, 1985:16) Commercial and housing were the main activities taking place in the block, whereas the open space was used for gatherings and meetings. On the other side, community and public facilities, like the theater, the gymnasium or the Agora (Market) were clearly separated from the urban blocks.

The case study selected for this period is Priene, a city in Ancient Ionia. This example fulfills all the criteria and meanwhile Priene is “the most extensively excavated Hellenistic city in Asia Minor and an excellent example of Hellenistic architecture”. (FHW, 2012)

Case study: Priene

Priene was built around 370 BC, probably planned by Pytheas, the second most famous greek architect after Hippodamus. It was located southwest of ancient Ionia on a slope, today at the province of the district of Aydin in Turkey. Built in four levels, the city had 4.000 inhabitants.

The street network consisted of six horizontal main streets faced east-west and secondary vertical ones faced north-south, which created the orthogonal urban grid. Plots were equal (207.60 m² each) and the built area was equal as well. Each block had 8 orthogonal plots, each sized at 8x23 meters. Main streets were oriented for transition and trading activities. Inhabitants accessed their houses from secondary streets.

The urban tissue is a repeated image of urban form and architecture; equal blocks, houses and streets. The inner courtyard (40 m² each) is used as an atrium and was only accessible to the inhabitants for gathering, meeting and leisure purposes. Moreover, it was arranged in the middle so as to be accessed from all the rooms and served for natural ventilation of the house as well. The buildings for trade and storage were one floor high while housing was two floor high, so that living spaces gained sun exposure due to orientation and to the inclined surface.

The historical reception of Priene shows that the city was always considered as an ideal type of Greek Polis. Wolfram Höpfner, notes: “The high point of classical urban planning is Priene. This is the only case where the city can be considered as an enormous work of art.” (Höpfner, 1997:39)

Medieval City

After the fall of Roman Empire, many cities began to be deserted, while others were being destroyed by barbarians. During that time, Europe faced an urban growth and new urban settlements were built for trade purposes and craft industries; a polycentric and differentiated settlement pattern emerged. This pattern was consisted of specialized cities based mostly on trade. For this reason, the medieval city as we know it today has a relative homogenous image through the cities of Europe. Some, as Benevolo, consider it to be the base of the so called

European City (see Benevolo, 1980); following the argumentation of Max Weber, it is the base of European culture and the Western society because of the emergence of rationalism, capitalism and bureaucracy (see Weber, 1986).

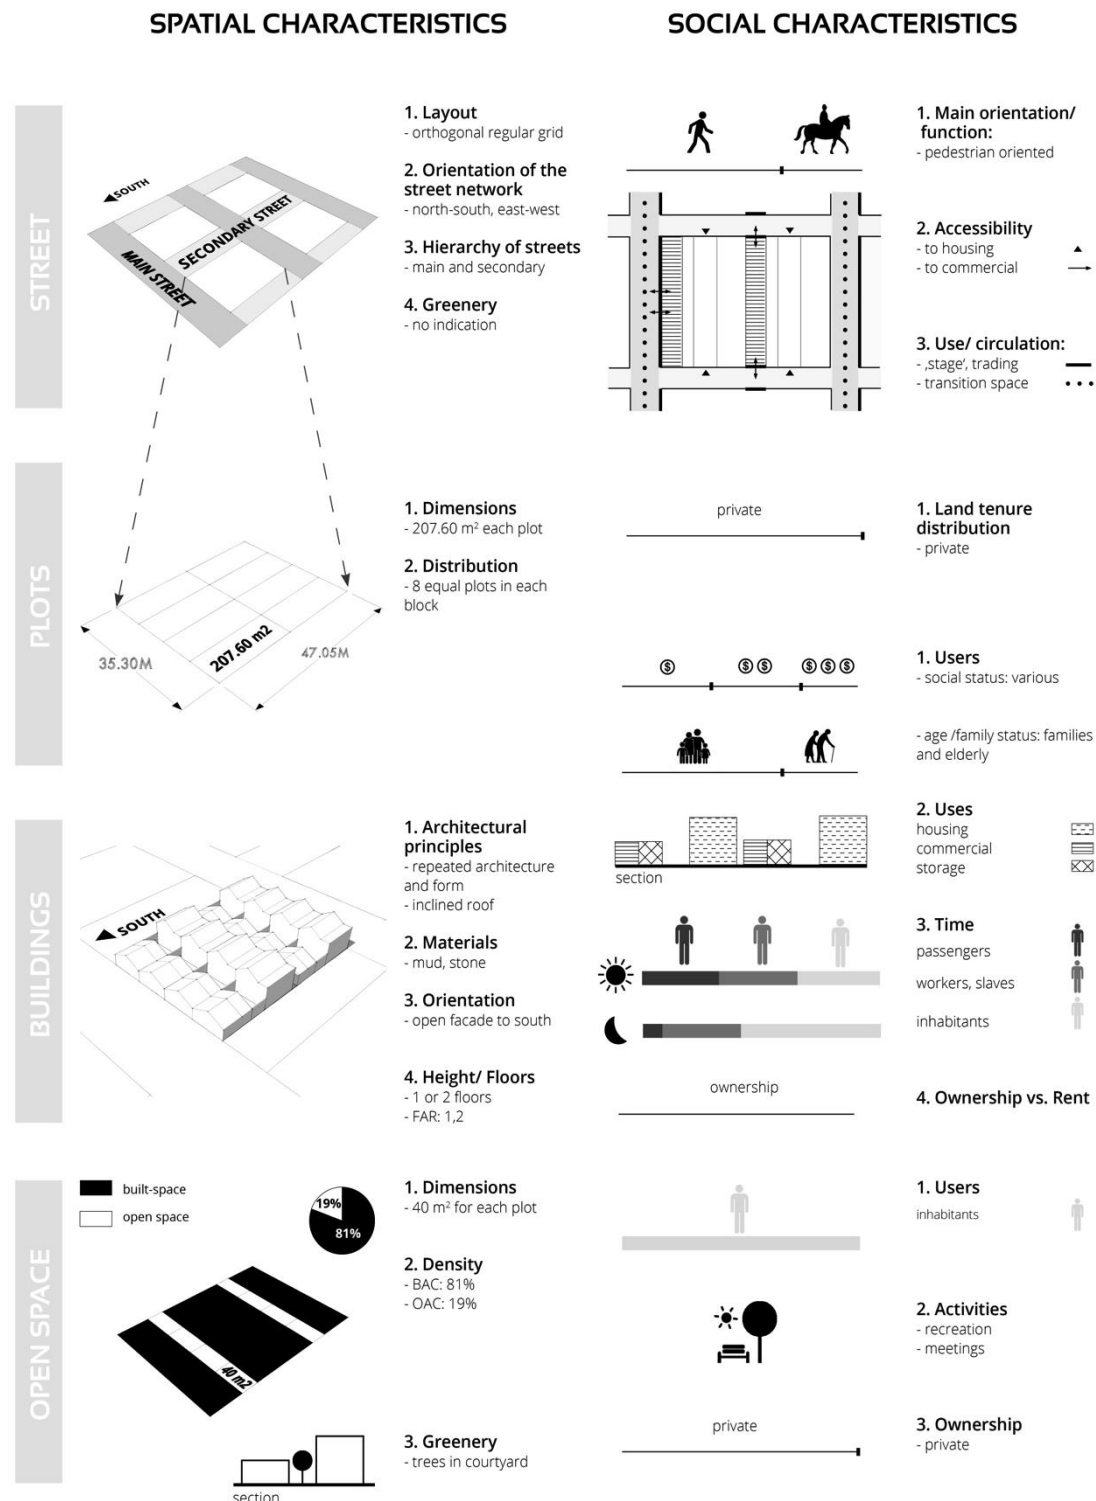

Figure 1. The urban block in Greek Polis. The case of Priene (based on Fischer 1920, Höpfner and Schwandner 1986, Höpfner 1997 and FHW 2012).

The most typical characteristic of the medieval city planning was the clear division between city and landscape. This division was also made possible because of the surrounding walls/fortification, which protected the city of future invasions. In many European old city centers that were not damaged during the wars afterwards, the medieval core is still visible in the urban layout. Another fundamental element of planning was the central location of representative places, such as main streets and squares with a cathedral, the dominating landmark of the city. The square around it became the most important market place, whereas open space was usually occupied by trade.

Other basic principles of medieval planning were compactness and narrow street network. The emerging layout was a labyrinth of irregular streets radiated from the central square and polygonal urban blocks with organic forms. Streets were used as transition and trade space; therefore, the division of the plots was of a great importance. Plots were small but elongated so that as many merchants as possible could have a front to the street.

The building forms were also different creating many variations of urban morphology. The individual plot with the house was the element which finally formed the urban block. "The irregular building lines of medieval towns testify to the varying status and power of the individuals involved". (Saalman, 1968:30) Furthermore, another typical medieval characteristic is mixed use; not only in the city, but inside the urban block as well. Different activities could be seen next to each other, inside the block, creating a mixture of working and living. There was also a social mixture of users such as merchants, craftsmen, bourgeois, and clergymen (see Hilberseimer, 1955:93).

For the period of medieval times the case study of Sagunto in Spain is chosen. Sagunto might not be a commonly known example for a medieval city, but it can be compared to other European cities, because of its convergent development that can be seen in the Roman background, the economical and socio-cultural characteristics and its urban layout.

Case study: Sagunto

Sagunto was founded and walled by Celtiberians around 500 BC. The town prospered because of the trade relations with Greek colonists and the Roman Empire. In spite of the destruction, the Roman influence can be still seen today at monumental expressions like the ruins of the Roman circus, the reconstructed Roman theatre and the castle on top of the hill, around which the old town is arranged. In 1098 the Moorish occupation caused a re-flourishing of the town (Ibáñez, 2012). The Moorish dominance was disrupted by the recapture by the Spanish troops (Reconquista) and was followed by a period of comparatively stagnation in medieval times. Nevertheless, there was a peaceful coexistence of Jews, Moors and Christians and a diversified social structure within the borders of the fortifications, which channeled growth enough to cause that densification typical for medieval towns.

Even though in the 19th and 20th c. warfare resulted in the destruction of the built environment, the urban tissue stayed persistent. The preserved urban fabric is characterized by a sequence of small squares, connected by curved streets that form urban blocks, which embed housing with small courtyards and churches. The aforementioned differentiated social structure within the medieval city can not only be found in the spatial separation of crafts and services, but it is also exposed in the built environment. Two different types of parcels, houses and connected ways of living can be distinguished; the Gothic house and the court-house.

The life in the Gothic house is organized along a vector going from the street to the inside of the block (see Figure 3). The first floor is meant for manufacturing purposes and main living room, while the second floor has secondary rooms for example for servants. On the contrary the life in the court-house is organized circularly around an inner court (see figure 3). The first floor is an entrance floor with stables, but it is not generally meant for living. It is a representative floor, which could be accessed through a main staircase located next to the inner court. No manufacturing function is found in the building, but some trade or commercial activities may be

present. In comparison the gothic house, it appears to be a more simple building for the working middle class that allowed for manufacturing and could be gradually expanded inside the block for needed additions. Meanwhile, the court house is a representative building for the upper class, with better living conditions. It uses the full plot size at once and incremental expansions for subsidiary buildings are not possible or needed like in the gothic house (de Armiño, 2012).

The chosen urban block is centrally located, its urban context is characterized by curved streets, main squares and churches and it contains the 'puerta de la judería', the gate to the Jewish district as well. It has a representative scale and combines both types of the described houses.

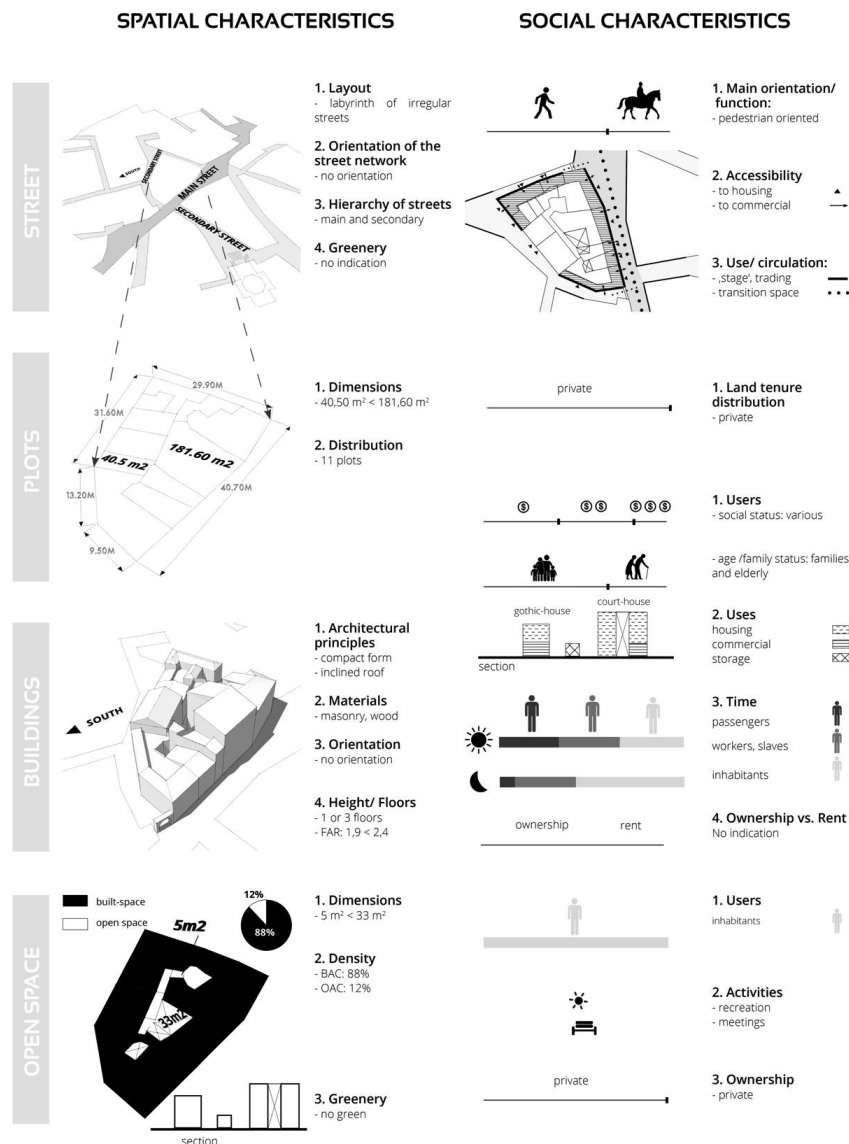

Figure 2. The urban block in Medieval City. The case of Sagunto (based on de Armiño 2012 and field study).

Figure 3. The gothic house (left) and the court-house (right).

Industrial city

Industrial revolution became the reason of the first mass rural migration in the history of urbanization because of the many work opportunities offered by factories and big companies inside the cities. The medieval city at that time had limited – if any – space for new housing and, in parallel, there was a remarkable population increase. Lack of housing was the main issue of that time and therefore city planning aimed to create adequate housing in the cities. As a result, cities grew up rapidly beyond the walls in order to accommodate the industrial workers and their families.

The unpredictable increase of the population led to compact cities where the car became dominant in the streets. Problems like the lack of water supply, bad quality of living and pollution due to industry in cities caused the negative aspects of the industrial city, i.e. spread of diseases, unhealthy environments and poverty. Concerning the housing planning issue, cities conformed with the return of the grid. The use of gridiron planning goes along with the rationalism of modern time and the increasing influences of scientific theories. Orthogonal planning of streets and blocks was, at that time, the easy and quick solution. The city layout became regular and strictly organized once more, with almost equal plot division. Kostof notes that this era projected the “modern metropolis as a limitless, gridded city extension of stringently regulated private development”. (Kostof, 1991:151)

The urban blocks were closed with a rectangular or squared perimeter whereas inside there were courtyards. The buildings were similar in type and form, relatively high (four to six stories), compact and mixed-use at the ground floor. It is essential to point out that one can observe a repeated image of the urban tissue outside the inner medieval city.

The case study chosen for the industrial city is Berlin; a typical example in the relevant literature and a historical urban extension in Europe. Berlin’s present urban layout is the result of the industrial era.

Case Study: Berlin

Berlin was the capital of the Kingdom of Prussia during the industrial revolution with a high population and economic growth at the time. Berlin became the center of Germany and a concentration magnet for new settlers from rural Germany.

In 1862 the Land Use Plan of the Environments of Berlin (Bebauungsplan der Umgebungen Berlins) is proposed by James Hobrecht, the chief of the urban planning police (Baupolizei). Hobrecht was an advocator of social mixture and through his plan he offered “a foundation for the development of both working-class as well as bourgeois districts.” (Bodenschatz, 2010:20) The plan proposed a circulation network with wide streets (25-39 m), radial streets which led to the centre, and a ring road. The streets surrounded big urban blocks with rectangular or orthogonal shape. The urban planning police issued in 1853 building regulations (Baupolizeiordnung) concerning the construction of housing in the blocks. These regulations regarded an authorization of up to six floor apartment buildings with a maximal height of 22m

and a minimum courtyard area of 5,34 m x 5,34 m.

Tenements were generally built by large landowners or private companies known as Terrangesellschaften, the forerunners of housing associations (Wohnungsbaugesellschaften) or today's real estate developers, which "used the building grounds to the greatest possible extent" (Sonne, 2009:6). As a result the urban blocks were built extremely compact with small courtyards, creating the phenomenon called as Mietkaserne (tenements); „the perfect matrix of slum landlords and abusive congestion" (Kostof, 1991:152).

The urban planning police in 1897 issued building regulations which were by far a better version of those in 1853. The example selected here illustrates these kinds of blocks. Berlin Block is a typical example of compactness and high density with open spaces that had no greenery often used for meeting places for the inhabitants or for crafts and workshops.

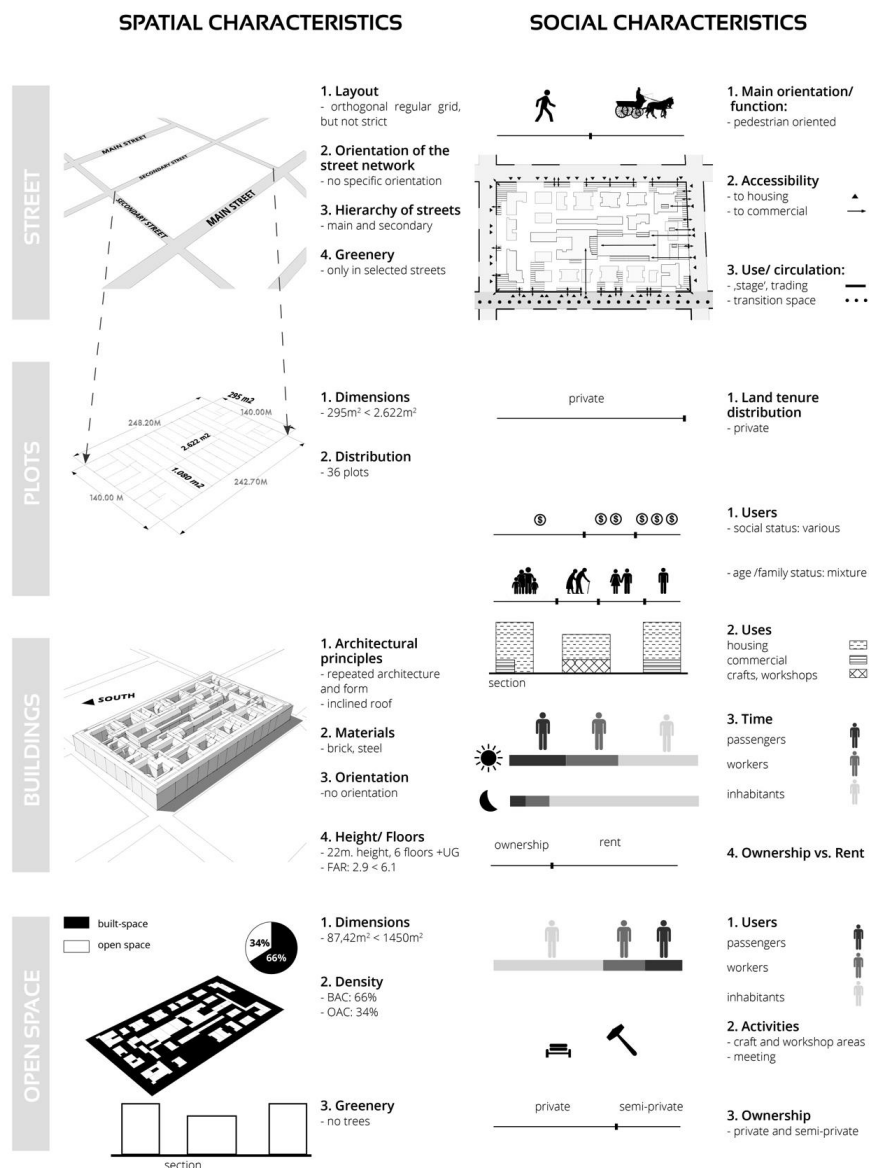

Figure 4. The urban block in Industrial City. The case of Berlin (based on Stübgen 1907, Hegemann 1988 and Reitzig 2005).

Modern City, early years of 20th. century

During the early years of 20th. c. began a systematic criticism of the industrial city, under the pressure of a radical immediate action that seemed to be of need after the first World War. Hence, the modern city appeared as the medicine of the unhealthy city. The goal was to improve the quality of living away from the industries and propose plans which promote the symbiosis of living and working in nature.

Ebenezer Howard was the founder of the movement of *Garden Cities*, also called satellite towns or “self-reliant communities” (Kostof, 1991:76). Closed and perimeter urban blocks were disintegrated. The plans of Garden Cities show an irregular city planning, where greenery seems to be the most important urban element. Few main roads, sprawled housing buildings facing cul-de-sacs and a parkway, which separated the commercial activities were the basic principles of the urban tissue.

Meanwhile, in the rest of Europe many extension plans were designed because of the ongoing rapid urban growth and new transportation technology. Centres were overcrowded and there was a mass need of housing. The solution was to expand quickly in the periphery. Hausmann’s monumental “modernization” of Paris during 1853 and 1870 influenced later extensions plans in other countries, such as the Netherlands, Germany, etc., where one observes wide streets, big urban blocks and similar facades on the buildings.

In late of 19th c. the evolution of social housing occurred in Vienna. “Vienna was again the first city to establish a competition for workers’ housing as reformed urban blocks.” (Sonne, 2009:74) The perimeter closed urban block with greenery in the inner open space (Hof) was the typical characteristic of low-cost housing for the working class. Later, the same planning principle was adopted to all the new structures for social housing, the so-called Gemeindebauten (municipality social housing complexes), and a new housing model occurred, the so-called socialist „socialist neighbourhoods“ (Sonne, 2009:78).

The case study selected for the urban block of early years of 20th. c. is the superbloc of Transvaalbuurt, in Amsterdam. This example illustrates the first intension of modern planning to propose open blocks in the city’s layout (see Panerai, 2004); a revolution, which influenced many social housing projects in Europe.

Case study: Transvaalbuurt, Amsterdam

After the approval of the Housing Act in 1902, which proposed loans to housing associations and supported the development of controlled housing production, the city of Amsterdam started to realize subsidized housing developments. Susanne Komossa observes that “the notion of ‘public housing’ as a social ideal and a task for social reform was born” (Komossa, 2010:63). The largest public project was the extension of the south part of the city by Hendrik Petrus Berlage. Berlage made an initial plan in 1905 but in the end it was not implemented. Finally, his plan Plan Zuid (Plan South) in 1917 was accepted by the city of Amsterdam, which consisted of a new ring railway, orthogonal regular grid, wide streets and mostly long perimeter superblocs (50mx200m) for social housing. What we have already examined in the urban extension plans of industrial city, can also be observed in the case of Berlage; “a clear structure of the new quarters, a clear-cut separation from the old development and a station opposed to the old city” (Panerai et al, 2004:70).

The selected urban block is the superbloc Transvaalbuurt designed by Hendrik Petrus Berlage, Jan Gratama and G. Versteeg. Transvaalburt is a social housing complex built between 1903 until 1931.

The layout of the buildings shows the tendency to split the superbloc into smaller urban blocks. In this case, the superbloc has been divided in six smaller perimeter blocks which are connected with secondary streets and open spaces. „This hybrid urban form was transformed into urban standard in the south of Amsterdam” (Sonne, 2009:91). The block has turned from a large elongated closed superbloc to a combination of smaller open blocks. Green spaces

located inside the blocks were accessed by the public community. As Komossa notes: “the public realm became the collective realm” (Komossa, 2010:66).

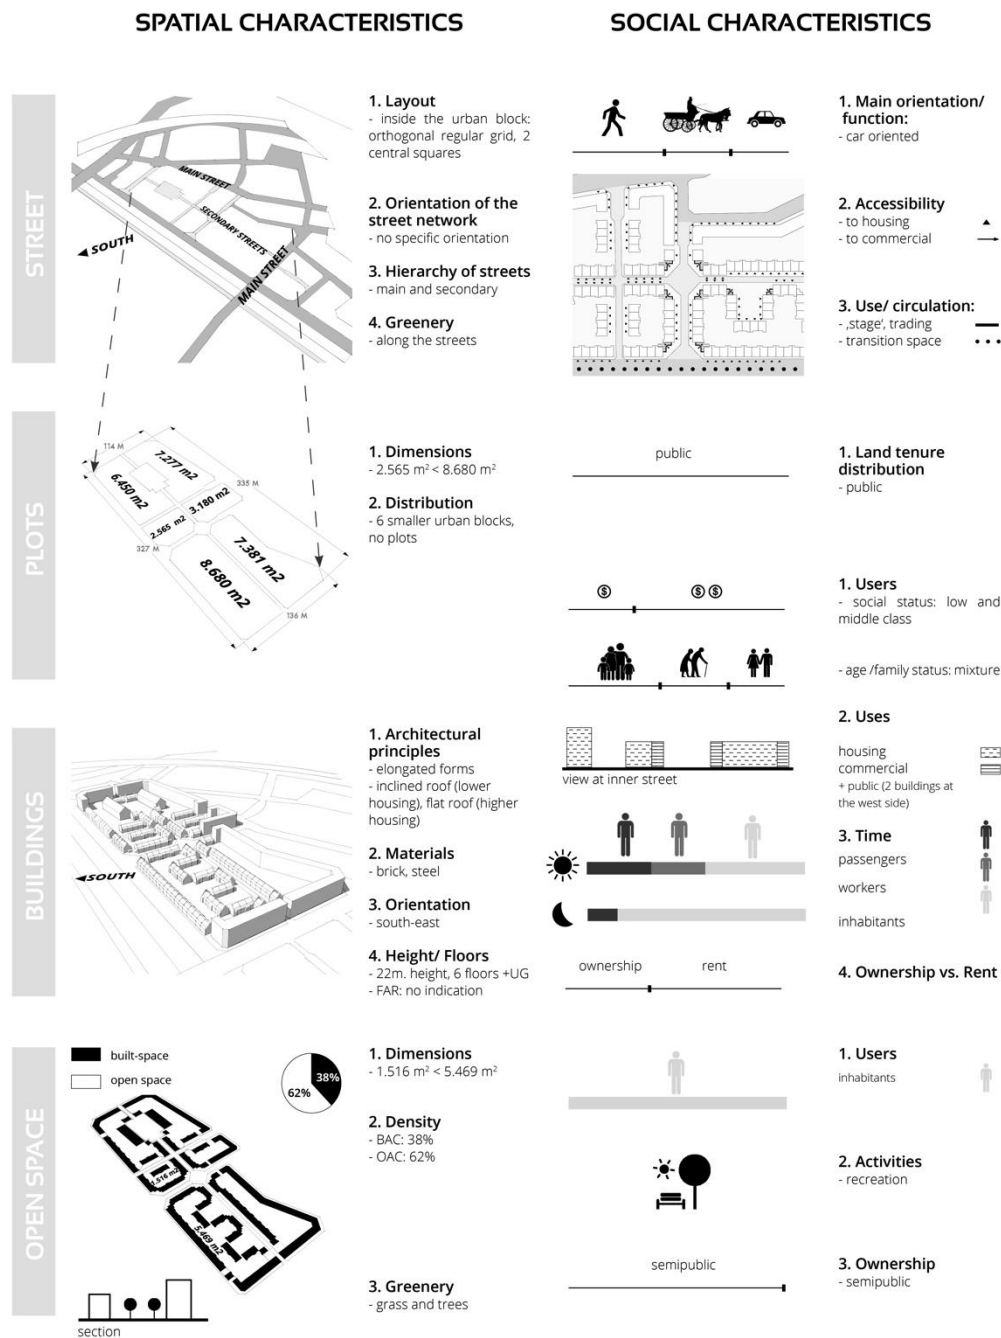

Figure 5. The urban block in early years of 20th. century. The case of Transvaalbuurt (based on Sonne 2009 and Komossa 2010).

The buildings which face the main streets are higher, whereas the lower buildings are located at secondary streets and along the canal. These continuing facades was a typical characteristic of early modern planning, showcasing the important of the street walls. Komossa explains: “The composition of the façades emphasized the continuity of the street walls and the urban space rather than the volume of the actual block, and this was accentuated by having façades that were

identical in height.” (Komossa, 2010:71)

At first glance Transvaalburt seems to be a large housing complex with a modern urban layout. Although the inner area of the neighborhood had more of a village character, by observing the dimensions of the united buildings one can conclude that the urban set is the city. Transvaalbuurt is like a small city, a combination of metropolis and town (see Sonne, 2009:88-91). To sum up, this kind of blocks are the highlight of early modern planning due to the fact that they integrate spatial and social characteristics in a great balance.

Modern City, middle years of 20th. century

This period refers to clear division of activities and to the contradiction against the traditional compact - mixed use city. Buildings were sprawled in the open space but in the same time they were highly dense in height. Green spaces were located through the buildings and streets dominated the city layout as the car became the essential transportation means of mobility.

Ernst May together with other architects at that time e.g. Walter Gropius, Bruno Taut, Otto Haesler, etc., were representatives of the so called *Neues Bauen* (New Building) movement. Ernst May's new plan of New Frankfurt for social housing in 1925-1930 is a typical example of modern urban planning in Germany. “May created a synthesis between the environment of the garden cities and the vocabulary of modern architecture” (Panerai et al., 2004:108). Housing was constructed in rows which were repeated, so as to be built fast and to form a continuous image of the urban blocks. New residential districts (Siedlungen) show the homogeneity and the functionalism of the new urban blocks, whereas an obvious denial to compact mixed-use closed perimeter block. The modern model of housing proposed a new urban development based on healthy sprawled identical housing and “on the affirmation of an internal logic, independent of the contextual conditions of the site.” (Panerai et al., 2004:110).

During the same period in 1924, Le Corbusier, the pioneer of modern movement, wrote the book *Urbanisme*, a contentious manifesto about city planning. He expresses his disagreements concerning traditional cities, which represent disorder, chaos and danger (see Le Corbusier, 1971). He proposes plans for the contemporary city, where linearity, street network, open space and mass housing are the main planning principles. (see Le Corbusier, 1971). Some years later in 1943 *The Charta of Athens* was published and until today it remains one of the most controversial documents of the modern movement concerning the functions of modern cities. The suggested model of urbanism is quite a contrast to the importance of the historical city, and promotes architecture instead of urban morphology. The core idea of the document splits the city into zones and four basic functions i.e. dwelling, recreation, work and transportation.

Unité d'Habitation has been chosen for the last typology of the urban block for one essential reason. It is the perfect example of decomposition of the traditional perimeter block and a newborn type of urban form.

Case study: Unité d'Habitation 1947-1952

By studying on the example of Unité d'Habitation one can not refer anymore to a composition of several elements but only to a predominant characteristic: the building or the solitaire. Scholars like Panerai describe that Le Corbusier's planning represents the “negation of the city” or “the death of the urban block”. (see Panerai et al, 2004:121) Le Corbusier believed that the materials of urbanism are the technical possibilities of the machinist era and the nature, especially the 24-hour solar cycle. Moreover, he accredited the primary role to the architect-urban planner, who is the regulator of the new modern city.

In his book *Urbanisme*, he notes the planning principles based on which he built Unité d'Habitation: “It is a simple matter to build urban dwellings away from streets, without small internal courtyards and with the windows looking on to large parks; and this whether our housing schemes are of the type with “set-backs” or built on the “cellular” principle”. (Le

Corbusier, 1971:163)

Unité d'Habitation was designed to house 1600 residents in 337 units in 18 floors with an accessible public roof terrace; 165 m long, 24 m deep and 56 m height (see Fondation Le Corbusier). It is a monolithic high built unit, set-back in the middle of the plot, west-east oriented and based on pillars which form a pilotis. Open space is full of trees, greenery and walking paths, whereas parking areas dominate the urban environment.

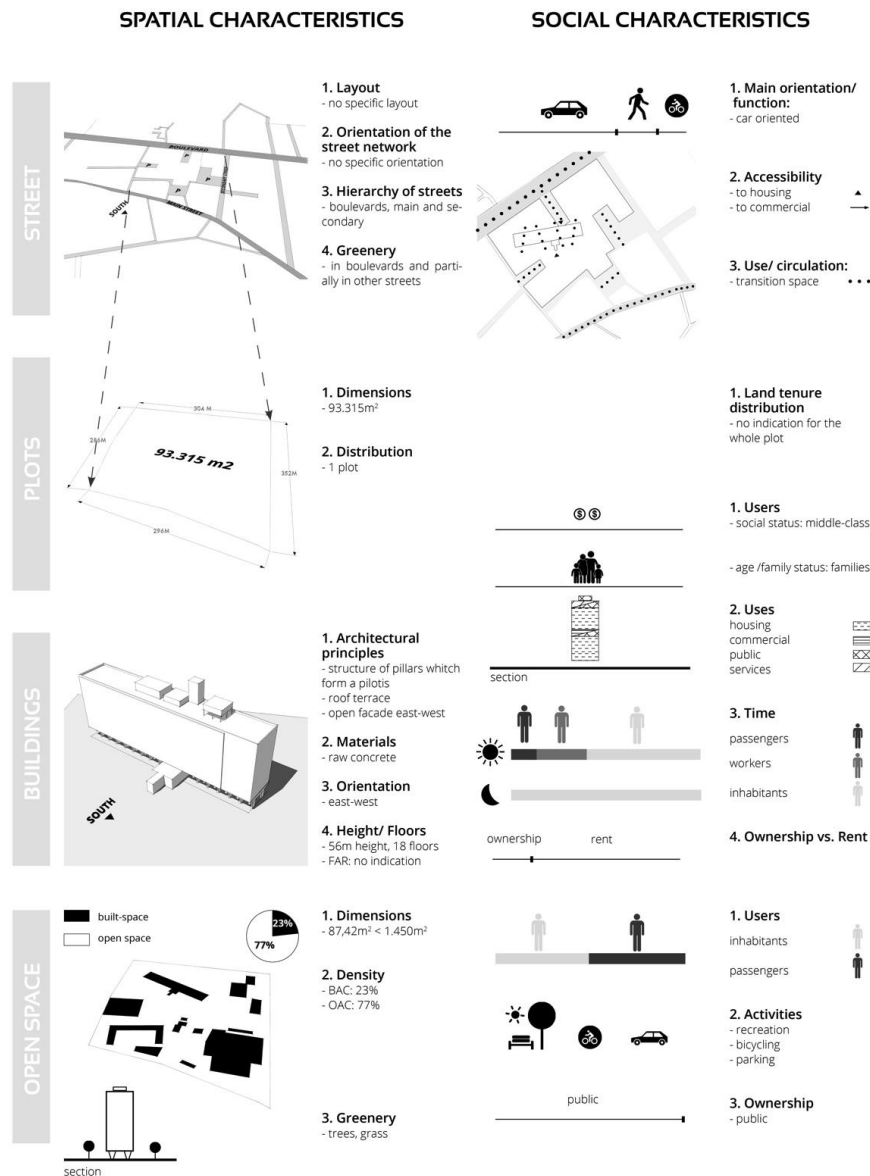

Figure 6. The urban block in middle years of 20th. century. The case of Unité d'Habitation (based on Panerai et al 2004, Janson and Krohn 2007 and Fondation Le Corbusier).

The urban block is totally opened; it has lost its traditional urban form and its interconnected social characteristics. The building is a part of a large urban block, where solitaires are seemed to be accidentally arranged in the plot. Spatial characteristics and social qualities are packed into a solitaire, into “a building that is a town” (Krohn in Janson and Krohn, 2007:7). Panerai and his colleagues observe another interpretation of Unité d'Habitation; the vertical urban block. “The traditional elements of the block are cut up, rethought, reorganized in that new unit, which appears to us as a vertical urban block, where all relationships are inverted and contradicted”

(Panerai et al, 2004:117-118). Public facilities like kindergarten and nursery are incorporated in the building as a mixed-use functional structure. Other facilities like commercial, post office or gym are located inside the unit as well. This small dense city, hidden inside a concrete megasilhouette, is like a secret place, which only the inhabitants know about it.

Conclusions

The first impression revealed by the comparison of the analyzed case studies is clearly the obvious difference in size. While greek polis and medieval city are still defined by a comprehensible dimension for the human observer, from then onwards the urban block has grown to an object of the implemented plan. Step by step the human scale was replaced by a hardly at once perceptible, a rather elusive urban element.

Additionally, the remarkable change in terms of density can be emphasized after comparing the diagrams of built and open space. The formerly clearly prevailing build-up area decreased in a gradual manner, while the open space became a larger and better useable part of the urban block - firstly within the block, and in modern times as a surrounding of the solitaires. This effect was accompanied by an increase of plot size, the improvement of techniques and materials as well as the resulting enhancement of the building typologies and the expansion of the urban block itself.

What is essential to point out is the transformation of the morphology of the blocks. Until the timeframe of the industrial city, urban blocks were formed by a closed perimeter space subdivided in plots. In the early modern city, the block is formed by a large collective unity of elongated buildings or smaller open blocks, where the inside of the block "becomes a passing place, accessible from outside" (Panerai, 2004:130). Until this point in history, urbanism was defined by the adjustment of the buildings inside the urban block as the main element of the urban fabric. This process of space production was replaced by the free standing *solitaire* in later modern city; the block is dissolved. The building, as a product of an architectural model, stands in an undefined space with no contact to the streetscape by setting back.

The historical comparison shows the persistence of mixed uses within the block until the separation of working and living since the late industrial revolution and the rise of social housing. This went along with a decrease of the importance and liveliness of residential areas by their functional separation. However living conditions were improved, although through focusing on the middle class, even the urban poor gained. Additionally the change of transportation systems caused an increase of quality of life. In contrary, this led to the emergence of transition spaces within a build environment that was not planned as a socio-cultural space of interacting individuals.

All in all, spatial aspects are based on the limits of the environment, the technical possibilities and the social, cultural, political and economical conditions. In a continuous change the interaction of requirements and opportunities promote the transformation of the build environment. Due to this belief, social and spatial characteristics are perceived as complementing and interacting to one another.

Although the examples of Priene, Sagunto, Berlin, Transvaalbuurt and Unité d'Habitation represent a long timeframe of the history, the research shows straightaway that urban forms have not transformed in the way that social relationships have changed. The metamorphosis of the forms of the blocks follows a relative normal process, whereas the alterations of social characteristics are always consequences of other complex relationships and systems in the city (e.g. economical aspects). In the final analysis, the five case studies showed that european cities have similarities, but also differences, in both their morphological and social character.

Morphology and structure of road crossings of the modernist urban ring of Viana do Castelo in the City's General Plan

José Lopes, Manuel Gulias, Rui Cavaleiro

Instituto Politécnico de Viana do Castelo

E-mail: clobes@estg.ipvvc.pt, mrivas@estg.ipvvc.pt, brancocavaleiro.arq@sapo.pt

Abstract. *The consolidation of both the medieval walled perimeter of the village of Viana (1258 to 1374-75) and consequent urban sprawl, resulting in its five suburbs (Moreira 2005 : 22-23), in the following centuries, led to a new ovoid shape. This happened due to either contagion or "technical culture" when designing the XVI to XVIII centuries streets and buildings centered on constructive sets of convents/monasteries and their Renaissance churches - the urban convent ring (Moreira 2005). In addition to this, the family mansions built on open ground and the lack of major geographical obstacles reinforced their growth and progressive urban spread along both ends of a main east-west axes (from São Vicente, along Rua da Bandeira, to Campo d'Agonia, through the former São Sebastião street), allowing the circulation of people and the establishment of trade, and thus, resulting in a wider relationship with the countryside and the outside world (Lopes et al 2013; Veloso et al 2012). It is this space made up of streets and urban buildings alongside the crossing of Minho's railway line (1877-78) that makes sense not only to the city planning (1848) but also to its map. Even before the railway line was built there was already an "urbanist sense" which led to a morpho- functional pattern expressed through the urban quarters which are defined by the street crossings, where access to drinking water has enabled the settling of people, houses, events and above all a better local circulation and contact with the surrounding areas. Our proposal is an analysis of the study and interpretation of the modernistic urban network, ex ante and ex post, of Viana do Castelo city.*

Key Words: *Modernist city, streets and blocks, road standard, urban plant*

Introduction

According to Saint Augustine, *cities are men and not the houses*. And in the case of the Viana do Castelo city this idea applies in full because its genesis is thought out and planned in the context of our founding of the nation, by charter of King Afonso III project, constituting a new ex urbe, from 1258 - 1262, County (Vila da Foz do Lima) with an original settler and then a mayor, both appointed by the royal power. Because that village now has its fortnightly Friday, granted by King Dinis, since 1286, and after getting walled requested contributions to its residents and those of neighboring counties, in 1374, the urbanity of Viana was consolidated and was projected this coastal territory north of the river Lee, and it progressively turned to the sea and sea trade in the following centuries.

The town of Viana in XIII - XIV centuries and has an inside perimeter of this ovaloid an orthogonal urban grid, usually led by the intersection of two main axes arruados and today are the Great and St. Peter Streets in east-west direction, and the Aurora Streets of Lima and Gago Coutinho, from north to south, and these converging at Largo João Tomás da Costa. Later in medieval outer zone and the urban plant sets new raster blocks but now contained by the union of architectural spaces of convents, monasteries and churches around that seem to foster care and health care material and spiritual to Viennese or wayfaring men, and that will generate another urban area, called about urban convent (Moreira 2005: 28-31).

This post medieval metropolis is thus an urbanized area, projecting around a corpus of political and administrative power and, above all, physical defensive structure and control all movements of goods and people on land transit from south to north or vice versa, as the sea into the ground and along the Lima valley. The territory north of Lima and our ocean front has

become safer with this póvoa of people, which started surfing because there were great concerns that drew navigation and mercancia, running with all its vessels to the northern provinces and islands, and achievements of Portugal, as tells us Frei Luís de Sousa in *Vida D.Frei Bartholomeu dos Mártires* (C.A.F. de Almeida, 1987: 77).

But this context of urbanity in growing with time and centered in this village, will be resumed and strengthened after about 257 years with the extension of this metropolis and its relational connection Roqueta Tower (1515), for, after so many years and then this place is well bastions in 1652 and 1700, the Fortress of Santiago da Barra is the emerging stage of the reputation of Viana, according to the civil conflict Patuleia and this result is a city under D. Maria II in 1848.

The modern and landscaped city of Viana do Castelo (1880-1910, 1911-1927, and 1928-1974) *ex-post* process to the passage of railway line

The urban period between 1793 and 1878 is the transformation of the metropolis, in general, in the anchoring of the old urban fabric with peripherals and surrounding blocks, generated by the street layout ordained between the center and the religious buildings and stately homes of the nobility, both military and civil, and wealthy merchants. It is *ex ante* process of Viennese city, a small outbreak of works and qualifications of its urban heritage stemming from the early port improvements (1867-1904) and urban public space intralocal movement (1891) and passing to other cities. Urban areas in the entrance of this period is shown in plan dated 1756 (Lopes et al, 2012: 115), where the old wall has the oblong shape to contain in its interior space orthogonal urban blocks, perpendicular and narrow streets because they were 3 feet wide and some less (d'Alpuim et al, 1983: 20), these blocks shredded into urban lots, usually 5.5 x 17.7 m, front and depth, respectively (Baker 2003: 63), but with an urban design with or determined by the regularity of relation to two main axes crossed, according to the cardinal points and its extremes were the ports of entry or exit from the village.

Moreover, this period is justified by the urban consequences of the demolition of the medieval walled fence (c. 10 mx 2.2) from the royal authorization - D. Maria I, 1793 and until passage of the path line iron- through opening of the first metal bridge roadrail the country on the river Lima (1878), two trays, in 1882 to reach the train station to the Viana (d'Alpuim et al, 1983: 51), ligand the city of Porto to the international border of Valencia.

With this new urban area, dictated by the train rails and flanked by granite embankments or walls in stone, there is an urban form that can configure a double combination (internal and external) urban networks, and the orthogonal radio- concentric, the latter forced or perhaps disguised by the natural relief that the Viennese metropolis is generated and expands. Constructive and demographic growth of the village of Viana develops in connection to the historical center located at its periphery religious centers, or by constructive consolidation of pre - existing blocks either by new streets cobbled paths and then the stone walls of this (the Eirado in 1814, and the tower and arch of Mercy/St. Peter, 1816). Is this outbreak and urban improvement that dictated the constitution and internal organization nine districts (1829) this Village by the Viennese councilor (d'Alpuim et al, 1983 : 31), as well as the first public garden (1846), the source of the current chapel of Saint Catherine, in the so-called ' Dízima the dogs ' area, and palm trees in old picture postcards. Most authors describes the modern city in the period between 1880 and the 40s century. XX, and to signal the following period and since the '60s, called post- modern city where most reference is planned and according to urban ideals enshrined in the Charter of Athens (1933) urban interventions. But the Viennese urban modernism show up subperiods of socio - economic and institutional context dictated by promoting urban infrastructure associated with the political regime and the then ruling power. Hence the appointment of three contexts - the constitutional monarchy; the first Republic and the New State (Lopes et al, 2012).

In the first context is given relief to riverside open spaces and conquered the estuary from the marshland of Argçosa to dock Castle Bar with its public landscaping (1882-1911), about 78 acres, as the yards and squares in front of important buildings, house Quesados (1878), the CP (1882) station, Sá de Miranda (1885) Theatre, garden Ferdinand (1888-90) and also to the urban streets, with emphasis on connecting the city to Mount St. Luzia, via paved road (1890-91). In the second context stresses the influence of infra - structure implemented in your district hinterland, where the first hydro-electric use of Lindoso (1915-1922) and the creation of modern urban interventions of the republican regime, under cover of law and specific regulations particularly through new plans for urban improvement (still anchored in Dec 10, 1865), social housing (Dec. No. 16005, 1928) and the implementation of urban plans (Dec No 24802, 1934). It was thus that sued the urban development of the resort of Mount St. Luzia, the opening of a new avenue of Fighters (1917), the construction of the funicular St^a Luzia (1923), the commercial extension to the Dock (1924) the qualifications of the public garden (1936-1940). But it is in the 40s and following the scheduled and more constructive urbanization was felt at the fabric of the city, through the following cases : the plan of Architect João Faria da Costa to St^a Luzia; the plan of Architect João Aguiar, for the District Flag (1943) ; the plan for opening avenues D. Afonso III and Américo Tomás ; the plan of Architect Paulo Cunha, for the sea port (1944) ; and the plan of Architect Gennaro Godinho, for the National High School (1946). And also the establishment of new urban neighborhoods generally dictated by lack of response to economic and social needs of the urban population, such as the renowned neighborhood - garden (1939, 1959), the Bairro dos Pescadores (1949-50), Quarter of Welfare (50), and Neighborhoods of Mercy (1968), adjacent to the old Technical School and the other in the streets of Santiago and General Luis Rego sector.

Analysis of urban and public space postmodernist: the network of streets, intersections and urban blocks

The development of public space within the boundaries of the historic center of Viana do Castelo is full of representative architectural examples from the 60s and subsequent decades. This diversity and mixing various epochs that mark the image, identity and history of Viennese urbanity, allows to understand and observe the evolution and development of its space and urban structure in the specific case, the post- modernist era.

In addition to this amount and diversity of architectural forms dispersed by city knitted Lopes et al, 2012: 125-128), are notorious three (3) urban spaces of dimension and relevant scale compared with other urban area, which occupied the existing gaps in urban structure height. And our focus is centered on the shaft adjacent to urban road - rail zone.

The first is located on the so-called "dry river" near the current shopping center ' Viana Station ' (2003). In this area, confusing urban design, partly due to the existence of the railway crossing and consequently, were built multi - residential building construction and aesthetic very similar. This area of high topography, connecting the city with the lowest elevation to high elevation, grew buildings with high volumetric which together have shaped the road structure and adapting to the requirements and limitations of terrain features. Its urban form is confusing, however routes crossing this area are important pathways in communication, transmission and interrelationship of people and goods in the public space, allowing the enjoyment of the center to the periphery and vice versa. This area stands out the building known as building Makonde" whose structure adjacent urban space designed at the time, recently allowed the opening of a new link from the city to the west (the Campo d'Agonia).

The second area identified is located on the block where the Hotel is located Rally (1970), and the facilities of the PSP, the Public Security Police, near the overpass of Sto. Anthony (1985-86, one of the main access roads to the city). This block is a block large compared with other urban fabric. This is because your inner" core", is filled with extensions of the buildings that make up the front of the street or urban front. Are generally warehouses which are activity

along with the rest built area occupies a considerable part of the urbanized area of the city. Have been the route of the railway line and the proximity to this equipment dictated the scale of this block? Easily observed through the architectural styles present, we are facing a consolidated urban structure whose concerns of the postmodern era, in our case, it supplanted the need to deliver quality public space environment, specifically through the implementation of buildings public character whose duties correspond to the needs of the time they were constructed (60, 70 and 80). As an example we highlight the petrol pump however demolished to make way for the aforementioned park hotel, the Palace Cinema (1947) that so many generations of Viennese welcomed, now transformed into an office building, the Garage - Car, currently the Peugeot brand, with its facade clearly designed to serve and reflect their function, and others. This area, in our opinion, deserve in the future, depending on its urban developments and their potential interests, an urban planning study to better linkage with the remaining area of the city, contributing to improving urban enjoyment between center and periphery.

The third area is located near the Eiffel bridge access and deployment of existing buildings created a garden space, today transformed into a “roundabout” (2004). The structure of this area is characterized by the presence of large building volume and primarily residential in character, with the exception of the then Hotel Afonso III (1971), now transformed into a multi - residential building.

These three areas, which are characterized by curiosity absorb three distinct areas, the road connecting the center with the periphery in different directions, breaking the continuity of the urban environment that is experienced in the remaining image of the city, contributing to the visual diversity of environments observed. When you traveled or crossed, these areas reflect the spirit of the age in which they were designed. The streets have wider than existing streets profiles (Table 1). The walks are wide and airy. The scale of the city suddenly becomes, grows, envelops us, but do not affect the relationship with the rest of the urban structure, by contrast, entranham in such a natural way that sometimes this becomes perceptible change in the composition and diversity the urban fabric, which is the transposition of the medieval urban scale to urban scale modernist and post - modernist.

It is interesting that these areas are signposted along the road crossings of particular relevance to the urban structure of the city of Viana do Castelo. Are these crossings on the line iron (c. 7.30 meters Profile - Iberian gauge), essential for the flow of traffic from the inner city to the outside and vice versa. Crossings are made through the tunnel (eg Sto. Antonio) viaduct (eg dry bridge) and another under the Eiffel bridge as larger example to link the riverside urban marginal, first on the road Papanata after the park represented by Limia - urban park (60), and then the Plaza de Galicia, the Hotel park (1972). These crossings were up adapting to the characteristics of the motor and needs of pedestrians and we can consider them and interpret them as new doors of access and greater mobility to the inner city. These crossings and we also brought new roads that generally have adopted guidelines perpendicular to the dominant axis of which include the Flag Street which crosses the city from west to east. These new arteries counteract the movement of the pre -existing urban fabric, and are geared towards the River Lee, allowing a more effective approach to the town with this environmental structure and natural environment.

Conclusion

The cross-section of the railway line Minho is the end of the century, nineteenth, 7.30 meters, and this value can be compared with the reference and modernist urban streets of the city of Viana do Castelo, in other words, be your triple, the Iberian gauge railway, iron, value - system for tracing the modernist highways because the Warring Avenue, with c. 22.00 meters in profile, is its largest representation (Lopes et al, 2013). We have then in the study and analysis these two benchmarks here propose a default value or reference to correlate and distinguish the modernist streets of the city of Viana do Castelo, according to its time of construction and function in

urban morphology/plant city. And the figures in Table 1 should highlight groups of modernist Viennese streets of the city, if we associate with sectors or areas of urban intervention, either from home or another function as well as intra and/or inter urban mobility.

Table 1. Cross-sectional dimension of modernist streets in the city of Viana do Castelo.

Rua G. Luís do Rego, Bairro da Misericórdia	10,48	Rua Gen. Luís do Rego (south-west)
Serviços Centrais do IPVC, Rua G. L. do Rego	8,25	Lar da S.C. Misericórdia, (east)
Serviços Centrais do IPVC, Rua G. L. do Rego	10,03	Lar da S.C. Misericórdia, (west)
Av. Conde da Carreira, Casa Melo Alvim	19,90	Av. Conde da Carreira, junto da Rua dos Rubins
Av. Conde da Carreira, Palácio dos Wernecks	18,91	Av. Conde da Carreira, Casa-torre do Sr. Valença
Teatro Sá de Miranda (north)	12,20	Rua Major Xavier da Costa (north)
Av. Rocha Páris (northwest)	13,13	Av. Rocha Páris, junto do Largo/Casa de Stº António
Av. Afonso III, Casa do Dr. Ribeiro da Silva	17,79	Muro da Linha da C.P.
Av. Afonso III, Gab. Arqº Valdemar Coutinho	16,63	Muro da Linha da C.P.
Av. Afonso III, stand da Volvo	15,00	Muro da Linha da C.P.
Rua Abel Viana	36,08	Muro da Rampa da ponte Eiffel
Av Luís de Camões	16,38	Limite do Jardim público
Rua Martim Velho	15,32	Edifício Jardim (west)
Rua de Aveiro (east)	14,06	Rua de Aveiro (east)

Thus propose three distinct groups of streets, by association or proximity in the case made the following reference: those with a profile close to the values of the Iberian gauge c. 7.30 meters; those with a profile close to the value of 15 meters; and finally bringing together the values of c. 22 meters.

This analysis and proposal articulated here is a way of testing for a first explanatory zoom urban diversity contained in each Portuguese city and its internal organization to serve the human community that inhabits it or enjoys.

But in the concrete values identified arruado own profile relate to urban reality of the site and taken to measure its contingency ownership or management interests present there - the public and private space heritage. Hence a typological sort of sketched (and “postmodernist”) modernist streets of the city of Viana do Castelo and confirmed in further studies and analysis.

Urbanization in the Brazilian hinterland's 'forgotten century': growth patterns in Planaltina

Pedro Paulo Palazzo

Faculdade de Arquitetura e Urbanismo, Universidade de Brasília.

E-mail: pedro.palazzo@gmail.com

Abstract. *This paper examines the patterns of urbanization in Planaltina, a town founded during the period of economic slump in Goiás state comprised between the decline of gold mining in the late eighteenth century and the construction of the new state capital, Goiânia, in the 1930s. Laid out on a rough grid sometime after 1811, this town belies several key concepts of the "canonical" Portuguese-Brazilian city, such as site selection, lot proportion, and density: it was built by a valley, with wide and shallow lots having ample side yards, and its houses are often misaligned. These features are compared with preceding and contemporary towns in central Brazil, highlighting general changes in urban patterns during the pre-industrial nineteenth century throughout the region, as well as aspects unique to the case of Planaltina. Changes in regional highway networks, the introduction of the automobile and of the aeroplane predictably influenced the growth of the town. Starting in the early twentieth century, infill begins to occur, with lots being subdivided either lengthwise or breadth wise, as well as changes in the historic centre brought about more recently by the demographic and economic effects of planned extensions to the city.*

Key Words: Small towns, Urban growth, pre-industrial cities, Brazilian Highlands, Planaltina

Introduction⁴⁴

This paper examines the patterns of urbanization in Planaltina (Figure 1), a town in the Brazilian state of Goiás founded in 1811 and presently part of the Federal District (Figure 2), 35 kilometres⁴⁵ from the nation's capital, Brasília. Its initial configuration and subsequent growth challenge several assumptions regarding urban form in colonial and pre-industrial Brazil. It also sheds some light on a period of the hinterland's urban history that has received little systematic attention: that comprised between the end of the eighteenth-century gold rush and the modernization brought about by the railway and Beaux-Arts urbanism in the 1920s.

The following discussion begins with an account of the history of settlement in the Brazilian Central Highlands, followed by that of Planaltina. The description of the morphology of the town is organized according to its three structural elements: public space network, land subdivision, and building typology. From this, a reconstruction of the urban growth of the town through time is attempted.

Settlement of the Brazilian Hinterland

Territory and Frontier

The first recorded Portuguese expedition through the central highlands of South America took place in 1580. By the second half of the seventeenth century, successive slave raids, dubbed

⁴⁴This research was made possible thanks to a faculty research grant from the University of Brasília, as well as a research contract with the Instituto do Patrimônio Histórico e Artístico Nacional (National Heritage Institute, IPHAN), through the company Ábaco Arquitetura & Design Ambiental.

⁴⁵Distances are given overland.

bandeiras, had made the region well-known to the Portuguese, though not yet linked to any administrative unit (Vianna, 1961–1975, vol.II.2, p. 75) Around that time, small farmers from São Paulo had established rural settlements in south-eastern Goiás (Holanda, 1981–1989, vol.I.1, p. 293) Eventually, the bandeira of Bartolomeu Bueno da Silva found gold in 1725 on the site of Vila Boa, and in 1744 the Captaincy⁴⁶ of Goiás was established by the Portuguese crown.

Goiás was settled mostly along two highways—mere mule paths—connecting the western frontier to the Ocean, both running preferably along terrain ridges (Barbo, 2010, p.175): the Estrada do Nascente (easterly road) ran through Vila Boa, the seat of government of Goiás, then forked at Meia Ponte into the north-easterly Bahia Road and the Southern Road (Figure 3). From these, the North of Goiás could be reached only by means of oft-shifting footpaths descending the sharp rim of the plateau, so inhospitable to the Portuguese—and even to most Indians—that it was home to hunter-gatherer communities up to the late nineteenth century (Bertran, 2011, p.49)

The gold rush in Goiás lasted up to the 1770s (Bertran, 2011, p.252) Afterwards, a few mining towns disappeared altogether, but most declined or stagnated. Goiás experienced a more severe and longer lasting form of the economic slump that followed this decline (Furtado, 1977, p.107) This situation led to the widespread understanding of the nineteenth century in Goiás as being a ‘century of silence’ (Garcia, 2010, p.11) Indeed, at the beginning of the nineteenth century, Goiás was the least populous diocese in Brazil (Simonsen, 1937, v. II, p. 328)

Urbanization

Except for Meia Ponte - a commercial crossroads - in its heyday, no settlement in the Province⁴⁷ of Goiás before the twentieth century exceeded a population of 10,000. Vila Boa topped at 8,000, while the third largest town, Santa Luzia, had a mere 3,000 inhabitants; most other sites numbered in the hundreds. Even then, the towns’ populations could hardly be called ‘urban’ by modern standards; French botanist Auguste de Saint-Hilaire recorded that: “a few menial workers and merchants excepted, all of the inhabitants of Santa Luzia work the land, and come to town only on Sundays and holidays; thus, during the week, no one is to be seen in the houses nor on the streets”. (Saint-Hilaire, 1848, p.14)

Most towns in Goiás had in common the usual settlement and urban design pattern of the gold-mining, colonial arraial (village). The characterization of such sites has long been the subject of controversy in Brazilian Urban History. Historian Sérgio Buarque de Holanda’s famous essay comparing the gridiron plan of Spanish colonial towns with the seeming ‘unkempt’ character of Portuguese towns (Holanda, 1971), had a strong influence on the popular view of these sites as haphazard clusters of houses clumped around streams or hillsides. Historical and morphological research since the 1960s, however, stressed that, though lacking geometrical regularity, arrais were planned and regulated. Far from being arbitrary, their street pattern typically followed hill ridges affording control over their surroundings.

Because of this, lots would be rather deep—one such plot in Santa Luzia is over a hundred metres long. Urban lot frontages could measure as little as 2.5 meters, although widths from 4.5 to 8.5 meters were most common. This meant a prevalence of party wall houses, particularly in larger towns and cities.

⁴⁶ An administrative division of Portuguese colonies.

⁴⁷ The 1823 Constitution of newly independent Brazil renamed the captaincies into provinces, establishing provincial legislatures.

History and Growth of Planaltina

Precedents and Physical Setting

The post-gold rush economic slump began to revert in the 1880s. The whole Centre-West region of Brazil experienced then significant economic progress, doubling its population as well as its per capita income (Buescu, 1978, p.233). Growth during this period was driven mostly by the expansion of cattle ranching. This development preceded by several decades the arrival of the railway in Goiás, a conventional hallmark of modernization in Brazil, which only reached the state⁴⁸ in 1912. Even then, progress on the railway was sluggish: ten years later, construction had all but stopped at present-day Pires do Rio, more than 200 kilometres south of the state's southernmost major town, Santa Luzia.

It is in this context that the small community of Mestre d'Armas began to thrive. It was located near the highest plateaus of the Central Highlands, at an altitude of 950 metres, where the legendary junction of the nation's three major watersheds had attracted early explorers. Ragged mountains lie to the north-west, locking out the north of Goiás but for the gorge of the nearby Maranhão River. To the south, the wide and flat basin of the São Bartolomeu River runs into a rolling valley leading to the southern provinces. A sharp plateau rim to the north-east separates the area from the hinterland of Bahia.

The whole region was natively covered with altitude savannah vegetation. In the mid-eighteenth century, much of this savannah was ripe for pasturing, due to the invasive spread of an African grass. This landscape is regularly interrupted by rainforest outgrowing perennial river banks. Local climate is altitude tropical, with rainy Summers, while in Winter days are hot and nights are cold.

The old colonial highway remained the main regional thoroughfare, running through the village of Corumbá, 150 kilometres west of the site, towards the northern edge of the plateau, up to Couros, the closest urban centre, just 40 kilometres to the east. The other branch of the highway ran much further south, through the town of Santa Luzia 90 kilometres away with no direct road to Mestre d'Armas at the time.

By the time of the earliest known record of the local toponym, in 1773 (Bertran, 2011, p.289), the site was already inhabited⁴⁹ and known to take its name from the nearby stream, possibly named after an early settler in 1751 (Bertran, 2011, p.369). The earliest sesmarias⁵⁰ or land grants in the area were established from 1741, even before the closest towns (Bertran, 2011, p.307).

Founding and Village Growth

In 1810, the owners of three sesmarias in the Mestre d'Armas area provided for the establishment of an expiatory chapel on their lands. The dedication is recorded to have taken place on the 20th of January, 1811. Even though the chapel was founded five kilometres south of the Bahia Road—the exact position of the highway shifted through time—the area was a likely passage between the latter and the Southern Road, along a series of smooth valleys. This passage did not remain unexploited for long, and in 1838 a trail was opened linking Couros to Santa Luzia through Mestre d'Armas (Castro, 1986, p.20).

⁴⁸Republican Brazil borrowed the name 'states' from the United States in 1891.

⁴⁹The Portuguese word *sítio* can ambiguously mean 'site' or a small farmstead. The latter is more likely in the document cited.

⁵⁰A *sesmaria* was a title to a vacant tract of land granted free of charge by the Crown or the captaincy. By the eighteenth century, it had been standardised to one league in width by three in depth, requiring adjacency to an established highway. Actual dimensions varied, however, since non arable stretches of land were typically discounted from measurement. The system was extinguished in 1850.

It is known that by that time the site was no longer a cluster of farmsteads, but a proper village: a record of that same year reads that the provincial legislature was successfully petitioned for the arraial of Mestre d'Armas to be annexed to the town of Couros, leaving the jurisdiction of the more distant Santa Luzia (Castro, 1986, p.21). This suggests that the site of the chapel, comprising a stretch of land one league in length by half a league in breadth (around 18 square kilometres) donated to the Church, had been partly subdivided into urban lots. Further, it indicates that the pre-eminence of the former gold town, Santa Luzia, was waning at the edges of its territory. Conversely, the nearby town of Couros was then establishing itself as the most active trading centre in eastern Goiás.

Heyday and Decline of Planaltina

On the 19th of August, 1859, Mestre d'Armas was erected a district of Couros. In 1880, it was belatedly granted the corresponding parish status (*freguesia*).⁵¹ Accordingly, the chapel was enlarged, and a pillory was built next to it. At that time, however, Mestre d'Armas was still not considered important enough for its parish to be regularly curated, according to the Province Almanac for 1886.

Finally, on the 19th of March, 1891, the state legislature incorporated Mestre d'Armas as a town (*vila*). The incorporation may have been an acknowledgement of Mestre d'Armas's growing importance, so much so that it was beginning to overshadow its older neighbour, Couros—now known as Formosa. Indeed, the 1910 Almanac (Azevedo, 1910, p.171–172) has no entry for Formosa, but does have one for Mestre d'Armas. The latter is described at length and said by the author to have around 1,000 inhabitants and as many in its rural jurisdiction. This number is highly unusual in pre-industrial Brazil, where 80% of the population lived in the countryside; it is more characteristic of a thriving commercial town. This entry describes the town as having some one hundred houses built on five streets and two squares. This structure supports twelve craft shops and four stores.

Mestre d'Armas did not cease to grow during the first half of the twentieth century, even though it did not catch up on the industrialization process of the 1940s. Known as Planaltina since 1917, the town gained nation-wide fame when, on the 7th of September, 1922, the cornerstone of the future nation's capital was laid on a hilltop ten kilometres from the town. It was the first town outside the old state capital, Vila Boa, to have a power grid, in 1925, as well as a telephone line. In 1935, it was the first location outside the brand-new state capital, Goiânia, to have a functioning airfield, and was identified as a possible stop on a planned link between Belém, in the far north of Brazil, and Buenos Aires. Hosannah Pinheiro Guimarães, a Planaltina native, rose to become deputy governor of Goiás in the 1940s. In 1938, the century-old trail that linked the northern and southern highways was replaced by an unpaved road suitable to motor traffic. By then, the main east-west highway had already been diverted from its colonial course, so that it ran through the centre of the town.

The construction of Goiânia from 1932, however, heralded a time when the agricultural and ranching South became the political and economic power-house of Goiás. Planaltina suffered from this change in the economic make-up of the state. Its urban population growth halted at a mere 2,000 inhabitants, whereas previously small villages were surpassing 10,000. All of the public buildings in Planaltina were either finished or abandoned by 1942.

The construction of the nation's capital, Brasília, dealt the final blow to the prosperity of Planaltina, its urban area ending up within the borders of the new Federal District. The new motorway bypassed the town altogether. The attraction of Brasília stifled commercial and manufacturing growth, while migrant workers began to settle in large numbers in Planaltina, soon outnumbering the locals. The historic centre of Planaltina (Figure 4) is nowadays drowned

⁵¹In Imperial Brazil, the establishment of parishes by the Church typically corresponded to the creation of districts by the civil authorities, for census purposes

in a dormitory satellite town of over 100,000 inhabitants, while the pressure of the real estate market and the enduring fascination with modernity threaten its architectural heritage.

Morphology

Site

The location where the future town of Mestre d'Armas was to be established does not seem an evident choice. The town of Couros already fulfilled, since the late eighteenth century, the necessary commercial and administrative functions for the area. Additionally, Elias Manoel da Silva, historian in the Public Archive of the Federal District, claims that the more usual halt for cattle herders was at Lagoa Bonita, some seven kilometres to the north and closer to the highway (Silva, 2012, p.1). Both the Mestre d'Armas Stream and its affluent, the Córrego do Atoleiro (slough brook), which enclose the site on the east and south, respectively, are shallow and have a small output. This results in swampy banks, especially around the Mestre d'Armas (Cruls, 1947, p.128–129), and water that is unsuitable for drinking. Archaeological evidence, however, shows that such choice of site for construction, near heavily wooded river beds, was common throughout the area, and that builders avoided both the exposed plateau rims and the ridges where roads ran (Barbo, 2010, p.178).

Transportation seems to have played a significant role in the choice of site. Though not straddling the highway as a typical commercial town would, the location is no more than an hour's walk from the thoroughfare. Moreover, it lies at the centre of a triangle formed by the Lagoa Bonita cattle halt, the watershed known as Águas Emendadas, and the junction of the Mestre d'Armas Stream with the São Bartolomeu River. Though not the Golden Lake of legend stuff, Águas Emendadas is crucially the most convenient passage to the north of Goiás in the area, leading directly to the distant (570 km) town of Natividade, former county seat of the North. The São Bartolomeu forms a rolling valley due south of Mestre d'Armas: a prime location for cattle ranching and smooth passage towards the south. Most of the site has a gentle slope, between two and five percent, while near the church the slope goes up to eight percent.

Public Space and Monuments

The historic centre of Planaltina has three public squares, each with its hallmark public building. The São Sebastião Square, around the old chapel, is the original core of the town. The old elementary school, demolished around 1980, used to stand on one side of the Salviano Monteiro Square, just one block north of the chapel. The local historical museum opened in 1982 in the house formerly belonging to the mayor who was the namesake of this square. The Padre Marcigaglia Plaza stands at the easternmost edge of the historic centre. A huge parish church was under construction there in the 1930s, but work stopped when one of its walls collapsed shortly thereafter; it was then razed, and the present church was built on the same spot in 1980. The former town council building (Casa de Câmara e Cadeia) and the town hall are set on simple street corners.

On the southern part of the historic centre, a cluster of four large blocks is defined by streets of irregular width and alignment (Figure 5). The single east-west street, Treze de Maio, follows an almost imperceptible ridge in the terrain. The four north-south streets are very imperfectly aligned with the contour lines, while one of them, Quinze de Novembro Street, bends to conform more precisely to the terrain.

To the north and west of this cluster are seventeen rectangular blocks of a more even shape. These blocks are defined by streets which are of an even width, and laid out in a still imperfect, but more carefully orthogonal, grid.

In 1921, one or possibly two north-south avenues, broader than the other streets, were opened. The creation of Salvador Coelho Avenue, bounding the historic centre on its western

side and roughly following a contour line, is documented (Castro, 1986), whereas that of Marechal Deodoro Avenue, on the opposite side of town, can only be inferred from the formal similarity. Additionally, Floriano Peixoto Avenue, an east-west avenue as wide as the previous two, delimits the southern edge of the historic centre and may also date from this time. The lots placed along its northern edge do not conform to its alignment, for which the only references are a ridge in the terrain and the perpendicular intersection with Quinze de Novembro Street.

Finally, a street deviating from both prior grids was opened in 1938 as the start of the road linking Planaltina to the south, bypassing the former link through Santa Luzia. It was formerly known as Rua da Palha (Thatch Street), suggesting that this suburban development was lined with the town's poorest houses. The opening of the road seems to have been accompanied both by the extension of the existing orthogonal grid, and by the planning of a new street grid perpendicular to Rua da Palha, as testified by two buildings defining this new grid. A number of rectangular blocks were laid out in a 1966 master plan, entirely enclosing the historic core in a shell of sorts, of which the outer rim was to be a string of large free-standing public buildings.

Land Subdivision

Lot shapes in Planaltina are very different from the canonical image of Brazilian colonial towns. Instead of being narrow and deep, with attached or semi-attached houses, lots in Planaltina are often wide and shallow. Because an intense process of land subdivision occurred in the 1980s and 90s, most information on lot size was gathered from the 1966 master plan drawing (Figure 6).

The four blocks near the chapel used to have very large lots with irregular shapes, often encompassing the entire depth of the block, a very unusual feature in traditional Brazilian urbanism. Lots across most streets surrounding these blocks may have been part of the original subdivision, since their width is consistent with that of the lots inside the blocks.

A very different pattern of lot shapes begins north of Treze de Maio Street. These lots are much smaller and seldom extend the entire depth of the block; this can be known to be the original layout of the northern subdivision because lateral lot lines do not line up. The northern lots, therefore, are extremely unusual in that they are often wider than they are deep, a feature seldom seen in any traditional urbanism anywhere in the world.

A third, more conventional, subdivision scheme emerges on the eastern and western ends of the historic centre. There, lots adopt deep, though not very narrow, shapes. As noted before, at least the western part of this subdivision is known to have been established in 1921. On the eastern part, the earliest documented construction is the town council hall, built somewhere between 1926 and 1932, suggesting the subdivision was created in the 1920s as well.

The 1966 master plan introduced a new pattern of land subdivision, with strictly rectangular blocks harbouring much smaller lots intended for single-family affordable housing. Surrounding these blocks was a string of large lots for public and institutional buildings in the modernist, fully detached, fashion—not executed in its entirety. Demographic pressure and economic hardship striking the town's traditional families contributed to systematic subdivision of the traditional lots for the past thirty years (Figure 7). The result is that the present-day pattern of land subdivision has become more conventional throughout the historic centre, with lots much deeper than they are wide.

Building Typology

Only a handful of nineteenth-century buildings remain standing in Planaltina, the oldest reliable date, besides that of the chapel, being 1896 for a small house near the chapel. Until the early 1920s, all buildings conform to the standard aspect and distribution of Brazilian colonial houses (Figure 8): one-storey adobe buildings having a central corridor with either single rooms or suites of rooms on either side, and a common room at the back. Walls are whitewashed or, more rarely, painted, with the wood frame either left unpainted, or covered in pastel colours. Roofs

are invariably hipped and without gutters; their structure is unsophisticated. These houses are invariably aligned with the street frontages.

In 1926, the first known example of a transitional housing type was built on the newly opened Salvador Coelho Avenue, a former clinic locally dubbed “Blue House” (Figure 9). It consisted of a standard colonial layout with two side porches leading directly to a much enlarged and dignified common room at the back. It was later enlarged with the addition of an indoor kitchen—traditional kitchens were set up beneath an open lean-to in the backyard. That building was also innovative in that it displayed a classical façade in stuccoed and painted fired brick, topped with an attic hiding the roof. This pattern echoes eclectic house plans and façades built in larger cities since the second half of the nineteenth century, and attested in the state capital in the 1910s. From then on, eclectic and art deco features become common in new buildings. The most iconic examples are the eclectic town council building, completed in or before 1932, and the art deco town hall, inaugurated in 1942.

The rise of the transitional housing types thus occurs at the time of the last two urban extensions. This is also the period in which Planaltina experiences a spur of modernization, receiving a power grid in 1925 and a telephone network possibly a few years earlier—both being the first in the state outside the capital. This did not, however, mean the disappearance of the colonial housing type, which continued to be built at least as late as 1965, with a curious mix of traditional roofs and adobe walls, together with prefabricated steel doors and windows.

Following the 1966 master plan, a standard house design was proposed for poor families to build for themselves. It has a compact shape with gable asbestos or metallic roofs over fired brick walls, with or without a concrete frame. The interior, free plan usually accommodates a living room at the front, kitchen and bathroom in the middle and bedrooms at the back. More recently, two-story contemporary houses, large commercial buildings and flats have been transforming the skyline and density of the historic centre of Planaltina. Despite the current prevalence of narrow lots as a result of recent subdivisions, contemporary single-family houses will be detached whenever possible, even if this means leaving only the narrowest of passages on either side. They will also have front setbacks, often used to accommodate grade changes, and garages at the front. Despite all these changes, it is remarkable that a few recent houses still retain the traditional compactness of volume and hipped roof shape of their older counterparts.

Proposed Reconstruction of Urban Growth

The urban development of Planaltina since its beginnings in the early nineteenth century, up to its replanning as a satellite town of Brasília in 1966, can be tentatively divided into four stages.

In 1811, a small chapel was dedicated to Saint Sebastian on the left bank of the Mestre d’Armas Stream. As reported by Bertran, burials were taking place within the chapel grounds since 1812 (Bertran, 2011). Then, behind the chapel and away from the stream, an irregular grid of a single east-west street and three north-south ones was laid out, defining four blocks with large and irregular lots. This first step gave rise to the earliest urban settlement, recognised as an *arraial* (hamlet) since at least 1838. At this point, a road was opened from Couros to the north-east to Santa Luzia in the south-west, running through Planaltina at an unknown location; the present-day single bridge over the Mestre d’Armas Stream was certainly not the only crossing over the shallow, swampy bed in the nineteenth century. The original chapel is the only surviving building that can securely be ascribed to this stage. It was enlarged with the creation of a sacristy, consistory, and a new apse, when the settlement was elevated to a parish in 1880. In the following year, a pillory was erected next to the chapel, signalling that the São Sebastião Square remained the town’s most important public space.

At an unknown date, but certainly not later than the 1890s, this settlement grew with the establishment of a regular street grid to its north and east. The most trustworthy terminus *ante quem* for this extension is the reported construction date of buildings around the second square of Mestre d’Armas: 1895 for the present-day Casarão Hotel, and 1899 for the Historical

Museum, formerly the home of Mayor Salviano Monteiro Guimarães. In the twentieth century, the Salviano Monteiro Square became the main public space in the historic centre, where most civic celebrations were held. Considering this major role played by this new square, the fact that the pillory was built on the old square in 1881 suggests that on that year the urban expansion either did not exist or was still at a very early stage. This yields a fairly precise date range, circa 1880–1895, for the extension of the urban grid. Still, in 1910, the state Almanac reports only five streets in town, indicating that this new grid was still barely in its beginnings.

This second grid was extended around 1921, with the creation of two north-south avenues bordering the town on either side as well as an east-west avenue on the southern edge of town. The only documented public construction before that date, however, is the creation of a new cemetery a couple hundred metres south of the historic centre, in 1893. On the eastern Marechal Deodoro Avenue were sited the two largest public buildings of Planaltina. The first is the town council building, arguably built somewhere between 1926 and 1932 on the intersection of the avenue with Treze de Maio Street, the main street in the first stage of urbanization, leading directly to the old chapel. The second is the new parish church, begun in the 1930s, razed in the 1960s, and completed in 1980. The western Salvador Coelho Avenue held the old post office and notary, the largest grocery store in town (built in the first quarter of the twentieth century), and Planaltina's only medical clinic (1926) and pharmacy (1938). Between the avenue and the stream was built the town's power relay station, in 1925. Until 1966, whatever little construction occurred in Planaltina was almost entirely bounded between these three avenues, with the town hall (1942) likely spurring more northerly growth.

In 1938, the road to Ipameri spurred a south-west vector, with both a fledgling extension of the existing grid and the indication of a new grid aligned with the road. Even in such a small town, wealth distribution can be detected in the remaining housing stock. The largest and wealthiest buildings were concentrated on the western side of town, particularly around the two main squares; the far eastern Marechal Deodoro Avenue and Rua da Palha concentrated the poorest and smallest houses. In response to the strong demographic pressure following the construction of Brasília, Federal District government architects designed in 1966 a plan for the extension of Planaltina with single-family affordable housing blocks as well as a modernist string of free-standing public buildings intended to shield the historic core.

Final remarks

Despite the paucity of historical documents, morphological analysis can suggest a reconstruction of the growth patterns of the town of Planaltina. This reconstruction is a step towards filling the gap in the historical knowledge of Brazilian urbanization in the nineteenth century. It suggests that, even though written and oral records may be lacking, some information can be gathered regarding the stages and chief features of the urbanisation.

These possibilities notwithstanding, significant restrictions remain, due to the nature of such vernacular settlements of the pre-industrial era. Assigning dates to the historical events described cannot be done with morphology alone. Urban and architectural patterns are long-lasting, and older patterns often overlap with newer ones for long periods of time—thus, the earliest eclectic plans and fired brick structures are attested in Planaltina in 1926, but adobe houses with a colonial plan remain in use at least until 1965. All things considered, it is hoped that this example of mixed historical and morphological analysis can be extrapolated to other vernacular sites where the lack of systematic documents has so far hindered research on the origins and growth of Brazilian towns.

Hermann Jansen's *Grünstreifen* in Ankara and their transformation

Sinan Burat

Department of City and Regional Planning, Mersin University.

E-mail: burat@mersin.edu.tr.

Abstract. *Urban open spaces have been considered an integral part of urban space in modern urban planning theory and practice. A comprehensive urban development plan considering the green spaces as such were prepared by Prof. Hermann Jansen for Ankara, capital of Turkey, in 1932, after he won the development plan competition in 1928. Jansen proposed an extensive green space structure that provided pedestrian access to every part of the city and to the greenbelt as well. In the 70 years following the approval of the plan, this green space structure has been modified in various ways and transformed to uses other than its original purposes. The purpose of this paper is to trace the modification of this green space structure in general and to analyse the transformations of one component of this green space structure, here called Güven Park-Tandoğan green strip, some parts of which still remain. The modifications will be analyzed with regard to the primary objectives of the State, the insufficiencies of the legal system, the actions of the landowners, and the decisions of the Development Directorate.*

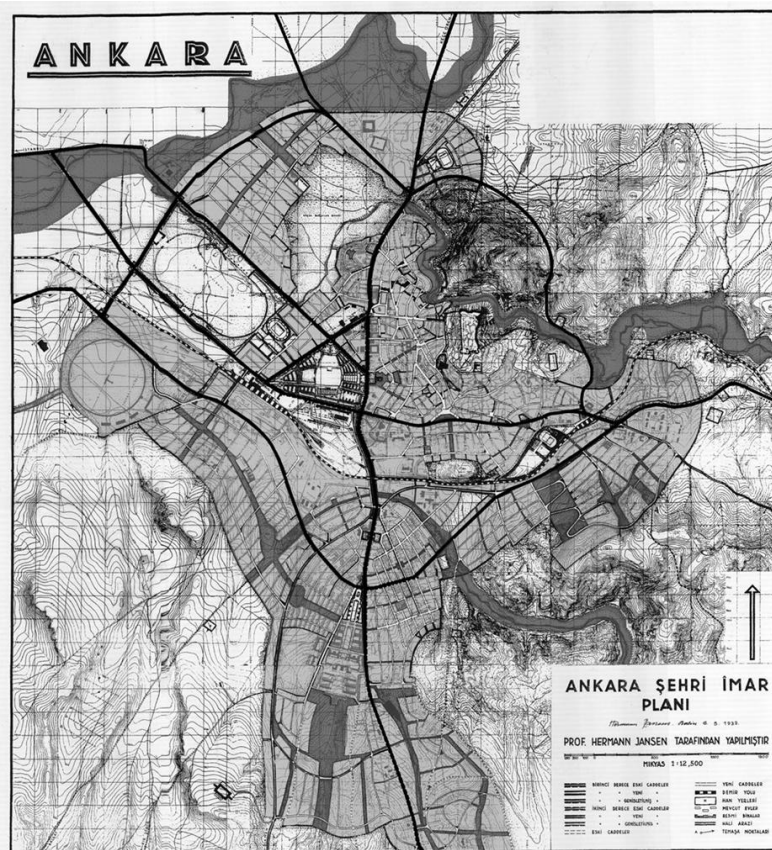

Key Words: Hermann Jansen, Ankara, green space structure, urban open spaces

Introduction

The fate of Ankara, an Anatolian city with a population of 20.000 in 1920s, changed with becoming first the command centre of Independence War and later becoming the Capital of the Republic of Turkey on 13th of October, 1923. The objective of the new Republic was to develop into a Western modern nation, and accordingly the policy of the Republic was to develop on every front into a fully fledged modern nation employing social, economical and spatial policies as well. To realise this vision, planned urban development, transportation, and industrialisation projects were initiated and run by the state, spreading over the country. The role of Ankara, as the new capital in this scenario, was to be the stage where the practice of the new social order, that is modern urban life, would be performed. This necessitated the transformation and development of Ankara from a small Anatolian village into a modern capital. New governmental offices, housing for bureaucrats and officers, new schools and universities, open and green spaces, and an urban plan that would guide their development were urgently required. To accomplish these tasks and to overcome the lack of local planners and architects to plan and guide the urban development of the new capital, foreign planners and architects were employed.

Lörcher was the first foreign professional to prepare a development plan for Ankara. The plan was put to immediate use, directing the first developments of Yenışehir (New City) area from 1925 to 1928. The only green spaces in Ankara in 1928 were Millet Bahçesi (Nation Garden) in Ulus and Havuzbaşı in Kızılay. The development plan of Lörcher was soon found insufficient from the points of the population projection and the insufficiency of planned area (Yavuz, 1980: 5). To obtain a new plan, an invited international development plan competition was announced in 1928. The experts invited to the competition were Hermann Jansen, Joseph Brix and Leon Jausseley (T.C. Ankara Şehremaneti, 1929; Tankut, 1993: 66-67). Hermann Jansen's proposal for Ankara was chosen as the winner, and from 1928 to 1938, the urban development of Ankara advanced according to Jansen's development plan approved in 1932.

that would serve as stages of representation for the new regime were readily implemented, those that would serve for everyday public use have been modified in the course of urban development or have not been implemented as Jansen has proposed. A green space having the quality of “everydayness” can be defined as a highly accessible, multipurpose green area, which can be used directly or indirectly on a daily basis for purposes other than organised events and sports. The “everyday” components of Jansen’s green space structure lacked the functional and spatial qualities to act as spaces of representation of the new regime, and have been modified for the most part. The green and open spaces of the plan which were employed as stages of representation of the power and achievements of the new Republic, or were directly designed as stages of representation, were given priority for implementation. The reasons behind this selective implementation and modification process can be summarized as follows: The importance and the role attached to the green spaces by Jansen have not been understood; the amount of the green spaces were found excessive and their implementation too costly by the development administration; and lastly, the state bureaucrats and the officers in urban development were involved in land speculation.

**Figure 2. Güven Park-Tandoğan green strip in Jansen's 1932 development plan
Jansen's Ankara Development Plans and the Green Space Structure.**

Jansen proposed an extensive green space structure composed of four types of green spaces,⁵² and integrated it into the larger urban structure. The components of this green space

⁵²The classification of the components of the green space structure is summarized from Burat, S. (2011) "Yeşilyollarda Hareketle İstirahat": Jansen Planlarında Başkentin Kentsel Yeşil Alan Tasarımları ve Bunların Uygulanma ve Değiştirilme Süreci (1932-1960) İdealkent Kent Araştırmaları Dergisi. Sayı 4, Eylül 2011. Ankara.

structure are:

Green strips (Grünstreifen): The green strips compose the backbone of the green space structure starting from the gardens of houses, maintaining pedestrian access through and to the periphery of the city, connecting first the green spaces with each other and with the residential quarters, and also letting the streams flow through the city. (Figure 3)

Central green spaces: There are three subtypes of these green spaces: i. Hippodrome and sports fields, ii. Urban parks, iii. Scenery parks and excursion spots. (Figure 4)

Allotment Gardens: Located nearby the workers' dwellings, these gardens and agricultural plots were reserved for fruit and vegetable gardening for the sustenance of the workers' families. (Figure 5)

Greenbelt: The city depicted in the development plan approved in 1932 is surrounded with an agricultural greenbelt (Jansen 1934a, 1936, 1937). The valley bottoms, and the lands around Çankaya, Dikmen, Keçiören, Etlik and Mamak settlements surrounding the city were reserved for orchards and vineyards.

According to Jansen (1936, 1937), the most important part of the green space structure was the green strips, starting from the front or back gardens of houses, reaching to schools, neighbourhood sports fields, markets and the Ministries Quarter, extending to the outskirts of the city and turning into scenic pedestrian roads in the agricultural greenbelt. These green strips, flowing throughout the city, was forming a network alternative to the street network, which was to be used by motor vehicles and pedestrians as well. For him, walking was not only a mode of transportation, but it was also the best form of exercise for the modern urban man.

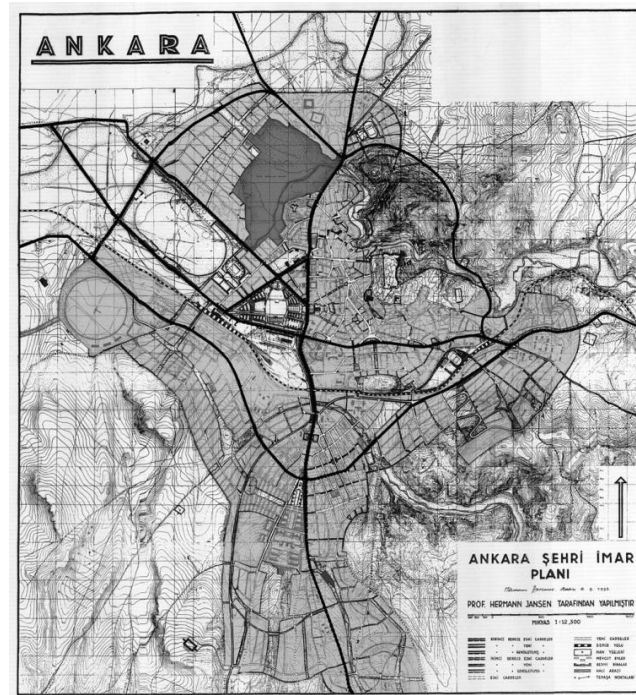

Figure 4. Central green spaces.

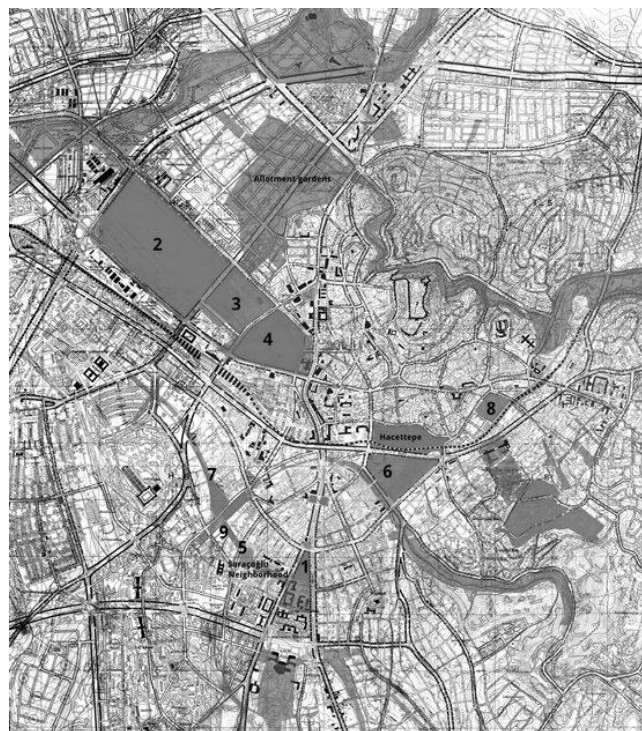

Figure 5. Allotment gardens.

The Urban Development and the Implementation of Green Space Structure

The first open space implemented according to Jansen plan was the Hippodrome (project by

Paolo Vietti-Viola), construction of which took two years to complete, from 1934 to 1936. Güven Park, opened in 1935, a park located in Kızılay, constituted the northern part of the Government Quarter spreading to the south of it and provided entrance to those approaching from the north of the city. May 19th Stadium and Gülbahçesi were both put to service in 1936, followed by the Seğmenler Park in 1938. Gülbahçesi and Seğmenler Park were the only nonrepresentational green spaces in this sequence, both of which were beyond the 1932 plan boundaries, close to the Presidential Palace. These parks are still present today. Gençlik Parkı (Youth Park) was the last park to be implemented until 1950s. Development of Gençlik Parkı took five years, between 1938 and 1943, and it was a very significant urban open space, positioned between Yenışehir and Ulus, the new city and the old city. As Uludağ (1998) puts it clearly, Gençlik Parkı was designed to introduce modern forms of recreation to the residents of both the old city and the new city (Yenışehir). Its location was therefore crucial, allowing easy access to the locals, the new comers, and the public officers. Considering the global economic crisis, the Second World War going on at the time, and the burden the cost of the park brought on the government budget, it must be stressed that the government was determined to create a park of this size (260.000 m² in the original design, of which 35.000 m² consists of a lake) and this character.

It was decided in 1952 by the Development Directorate that the development plan prepared by Hermann Jansen had become obsolete and a new development plan was needed for planned development of Ankara. After the preparations, an international planning competition was announced in 1954. The development plan prepared by Raşit Uybadin and Nihat Yücel won the competition and the plan was approved in 1957. The implementations from this year on have mainly been made according to this plan. A juxtaposing of Uybadin-Yücel development plan and Jansen's green space structure proposal illustrates the fate of the remaining parts of the green space structure. (Figure 6)

Maltepe Green Belts (as stated in the plan competition specification) cover an area amounting to 150.000 m² and have not been implemented (Ankara Belediyesi, 1954: 87). Out of these green belts, only four parks have been developed.

Neither the workers' housing, nor the allotment gardens located by the workers' housing were implemented. They were replaced with a light industry zone by the 1957 development plan.

Hacettepe, an excursion spot highly valued by Jansen to be saved as is, was developed into a health complex by various modifications between 1957 and 1967, resulting with one of the largest hospital campuses in Ankara. The hospital spread not only over the green space but also over several neighbourhoods that had an outskirts character at the time, which can be taken as a reason for replacing Hacettepe with a hospital (Cantek, 2006: 178).

Kurtuluş Park, one of the large parks in Jansen plan, was opened to use in 1960, after the development between Yenışehir and Cebeci neared completion between 1944 and 1956 (Altaban, 1987: 133). The construction of İnönü Stadium, which was a part of the sports complex in Cebeci, was completed in 1967, but the school and the sports field that Jansen had proposed as parts of the sports complex, was opened to development.

The legal and administrative structure needed to implement and manage the agricultural greenbelt that was defined in the plan report published in 1937 (Ankara Şehremaneti, 1937) and the 1/10.000 scale Ankara and Environs Plan have not been formed. The greenbelt has been considered a forestation area instead of an agricultural area, and its rather belated execution resulted in a set of scattered forestation areas encircling the city.

Starting with the announcement of the new development plan competition in 1954, six parks from Jansen's green space structure were opened to use by 1959, and twelve more parks between 1960 and 1969. By 1970, the population of Ankara had reached 1.236.152.

Gençlik Parkı (1938-1943), 5. Özveren Street Park (1956), 6. Kurtuluş Parkı (1960), 7. Ördekli Park (1964), 8. İnönü Stadium (1967), 9. Semih Balcıoğlu and Umut Parks (1967).

Güven Park-Tandoğan Green Strip

Construction of Devlet Neighborhood, which started in 1944, was the first intervention that destroyed the continuity of the Güvenpark-Tandoğan Green Strip. Lack of housing was an important problem in Ankara and developing mass housing for the officers was a project since 1933. Jansen developed several alternative schemes for housing for the same site that the actual mass housing was built upon. The difference between Jansen's alternatives and the implemented scheme of Paul Bonatz was that Jansen's alternatives kept Güvenpark and the green strip extending to East connected. The implemented plan by Paul Bonatz, also a German architect, on the other hand, destroyed that connection. Even though the implemented layout employs courtyard gardens, the connection between Güvenpark and the rest of the green strip lost its direct connection. This modification of Jansen's green space structure marks the start of a series of modifications.⁵³

The second and the third modifications took place in 1953, with the opening of the Şehit Gönenc Street and allocation of the Maltepe Mosque, followed by the Ayla Street development in 1954. Turgut Reis and Süleyman Bey Steets, two segments of a single street, cut through the parks as well. Since I have not come across a document containing information about their exact

⁵³ Güvenpark is not included in this analysis, even though it is a part of the overall green space structure. Güvenpark is an important part of the Ministries Quarter according to the original configuration of Jansen, a park symbolizing the War of Independence and being an arena of political protests, laden with different layers of meaning. It is also the largest green space in the city center, making it also an everyday green space. Having these qualities, the park has been modified in the past and is still a target for further modification, even development, and is a separate research topic in itself.

development date, I assume that they were constructed in or around 1953, with Şehit Gönenc Street.

In 1956, a gas station was allocated to the north of the Maltepe Mosque, bordering the Gazi Mustafa Kemal Boulevard, one of the most important traffic arteries. Hürriyet Primary School was constructed in 1956, the only plan modification made according to Jansen's proposal for school grounds. Also, 1956 was the year a park in this region, Özveren Sokak Park, was opened.

The last two plan modifications were the development of a workers' housing in 1958, and its replacement with sports fields later in 1970, none of which were realised. The final modification was made to allocate Maltepe Market in 1960. Later, in 2008, the market was replaced with an underground shopping mall called Malltepe (Mall-Hill).

To summarize, starting with Saraçoğlu Neighborhood development in 1943, Güvenpark-Tandoğan Green Strip was modified until 1960, diverging from the green pedestrian spine Jansen had visualised. It was converted to provide space for structures and amenities such as streets, a mosque, service buildings of district municipality, a gas station (that is replaced with a light rail station in mid 1990s), a car park, and a market (which later turned into an underground shopping mall) (Burat, 2008: 104-126). The green spaces left after all these modifications made to the green strip were four parks, which were opened to use between 1964 (Ördekli Park) and 1967 (Umut and Semih Balcıoğlu Parks). These parks cover an area of 26.000 m² out of the 150.000 m² of the original proposal of Jansen (Çankaya Municipality) (Figure 7).

Figure 7. Parks realised from Güven Park-Tandoğan green strip.

The Dynamics of Modification and Implementation

To understand the demand for urbanisation and the need for housing development and government building in Ankara, some figures about the population increase must be given. Squatter developments caused by migration from the rural areas to the cities began as early as 1935 in Ankara (Tekeli, 1980: 91). After the end of the Second World War, migration to cities

from the rural areas took place all over the country. By 1950, the population of Ankara had reached 290.000, almost reaching the 50 year projection of the 1928 development plan competition, which was 300.000 (Altaban, 1998: 47). Population of the city rose from 74553 in 1927 to 122720 in 1935, to 157242 in 1940, to 226712 in 1945, and to 228536 in 1950 (Tekeli and Güvenç, 1987). The number of people employed in public administration was 4920 in 1931, rising to 11836 in 1938, and to 24620 in 1946 (Altaban, 1987:31). While the population increase ratio for Turkey between 1927 and 1950 was 53.5 %, the rate was 206.5 % for Ankara. Today the population of Ankara is over 4 million. (Figure 8)

Against this backdrop, an evaluation of the implementation and modification process of the green space structure is offered below, taking into consideration the priorities of the republic, the legal and administrative problems, and land speculation.

Figure 8. The limits of first three development plans of Ankara and the present macroform of the city (Consecutively from inside out, Lörcher, Jansen and Uybadin-Yücel plan).

Priorities of the State

The production of the green spaces was carried out primarily according to the preferences of the Republic. The implementation sequence of the green spaces put forth that the green spaces produced prior to 1954 were of representational character, conforming to the modernity project of the Republic. According to this project, parade grounds and spaces for celebrations and ceremonies were urgently needed in order to create a nation state and to adopt the contemporary lifestyle and manners and to create a middle class (Tekeli, 1998: 4-11; 2000: 320-321). These representational open spaces provided grounds for celebrations and demonstrations on important days, national holidays, for organised sports events, which all displayed the power and the practices of the new Republic. Production of the components of the green space structure proposed by Jansen started with the construction of Hippodrome in 1934, and ended with the opening of Gençlik Parkı in 1943. Other than Gülbahçesi and Seğmenler, all the green spaces produced until 1943 served as spaces of nation creation and the stages to demonstrate the model of leisure and recreation practices of the modern citizen. The celebrations and the processions at the national holidays were held at the Hippodrome and the 19 May Stadium. 19 May Stadium was also the venue for the national and international sports competitions (Bozdoğan, 2001: 75). Güven Parkı, which was a part of the Ministries Quarter, narrated the Independence War and introduced the actors and the qualities of the new social order with the Emniyet (Security) Monument (Batuman, 2002: 52-53). Meanwhile, Gençlik Parkı (Youth Park) was a new place of

entertainment for the middle classes, as well as a place for the locals of Ankara to observe and to learn this new life, entertainment and recreation practices and to transform themselves into the new citizens sought by the Republic (Yılmaz, 2006: 213-219). In contrast to the importance given to the production of the representational spaces by the Ministries, the development administration fell short for the production of everyday green spaces proposed by Jansen. The green strips, sports fields and squares, neighbourhood sports complexes, all destined for everyday use, were the important components of the urban life Jansen had envisioned. Yet places like Hacettepe and the Güven Park-Tandoğan Green Strip, which both had the character of everyday green space, were extensively modified and diminished, as summarized above. It was not realized by the development authorities that these green spaces also had the potential to have a representational character, as they could serve as a platform for everyone to practice the youth and health cult that symbolised the break from the old regime.

Development Laws, Regulations, and Land Speculation

The development laws and regulations controlling the urban development were outmoded for a modern urban development plan such as Jansen's. Even though a new development law was passed in 1933, it was prepared under the influence of the one it replaced. The new law was not detailed enough and did not meet all the requirements to implement Jansen's plan. The development administration was trying to find solutions to these problems emanating from the law. A problem of this sort has surfaced during the expropriation of the market places and sports fields nearby the schools. A Development Executive Committee decision in May 1933 clearly expresses that marketplaces marked in the development plan were considered as amenities in favour of public interest according to the Development Law and their parcels would be expropriated, but as the law lacked any details of this kind regarding the sports fields, the decision was to make a request to the gymnastic clubs in Ankara concerning the appropriation of these fields. From questions asked to Jansen the next year, we understand that the problem had not been solved. When Jansen (1934b) was in Ankara in April 1934, he was asked about under whose ownership the sports fields beside the schools would be, and how and under whose supervision the allotment gardens would be rented.

Coupled with this problem was the increasing impact of the bureaucrats and officers of the Republic on the course of urban development. Even while the Hippodrome, 19 Mayıs Stadium, and Güven Park were being built, illegal constructions on sites that were designated as green areas on the development plan were condoned, and measures that did not conform to the plan were implemented (Tankut, 2000: 213). Those who could, got involved in land speculation and used their influence on decision makers for favours. In some instances, using the high expropriation costs as an excuse, plan modifications were made to decrease the amount of green spaces and to keep the plots of influential people out of green spaces (Tankut, 1993: 213). These modifications were made directly on the green spaces that were proposed for daily use of the urbanite, such as the green strips (Development Executive Committee, 1934; 1938) or the urban forest to the south of the National Assembly (Development Executive Committee 1937). Jansen (1936) had proposed this urban forest as a buffer to stop the urban development from coalescing into each other. In 1937, the decision taken by the Development Executive Committee (1937) decreased the width of the urban forest in order to remove the parcels of two deputies out of the no development zone.

The aim of the Republic, to develop Ankara into a modern capital city, was hampered by the insufficiencies of the development laws and regulations, and the land speculation and patronage relations in the course of urban development. The green space structure proposed by Jansen for Ankara has been extensively modified and realised partially in the form of parks, on lands leftover from the modifications. These separate parks are far from constituting the structure of the modern life Jansen had envisaged for the urban population of Ankara and the members of the modern republic. Car ownership increasing after 1950s and the new plans increasing the density of the city, which are not discussed here, have been the other important factors that led

to the modification of the green strips, turning them into streets and car parks. Today, the produced components of the green space structure are still under threat and the modification process of the green space structure proposed by Jansen is far from over.

Morphological process as an instrument for knowing chronological character: a case study in Tainan

Chih-Hung Chen, Woan-Shiuan Lin

Department of Urban Planning, National Cheng Kung University.

E-mail: chihhungchen@mail.ncku.edu.tw

Abstract. *The evolution of the historical process produced the morphological character of the place, which can be revealed in previous European studies. However, in Asian cities, urban morphology is rapidly altered by industrialisation and the evolution of social environment, such as population explosion in merely half century, lease the morphological structure not really apparently. Therefore, can the “morphological process” (Conzen, 1988) still be a perceive approach to illustrate the city form in East Asia in this era? So, we need to figure out what is the character of Asia morphological process? For the purpose of realising the evolution particularity, we need to find out the fringe-belt (Whitehand, 1987) and built-up area (Ünlü, 2012) as the morphological region which could may reflect the sequence of urban forms. However, in East Asia cities, the boundary was usually blurred by filling buildings with because of the increase population growth. Morphological process can be seen regarded as another evidence of morphogenesis, and therefore be used as an instrument to measure the sequence of urban formation process. With a view to knowing the chronological character of Asian cities, Tainan, an old port city which is located on the East Asia marine trade routes, had experienced the Age of Exploration, industrialisation and the post-war population explosion. The differences of fringe belt formation process and four types of morphological region which correspond to each period specificity will be revealed in this study.*

Key Words: *Fringe belt, built-up area, Morphological process, Morphological region, Tainan.*

Introduction

During the past half century, Asian urban area had experienced rapid industrialisation and post-war population explosion. In the next few decades, the urban areas are expanded and followed by the remodelling of existing settlements, which can also be regarded as the “*urban deformation*”. Generally, urban form can be viewed as the result of the competition and compromise between social and economic forces of every morphological period (Conzen, 1977; Harvey, 1989), especially in European urban studies. Nonetheless, in an even rapid process of urban growth in East Asian context, could features of each era still be recorded or presented by the urban form?

The related study of the evolution of urban form or so called “*morphological process*” can be summarized in three stages: “*Accumulation*”, “*Adaptation*”, and “*Replacement*” (Conzen, 1985), while every urban regions has their unique morphological process to adapt the physical as well as the social environment, and these processes may be recorded on space pattern. However, the chronology of urban development in East Asia is distinct form the situation in European city. Therefore, the methodology, by which space character can be defined through a certain morphological period, may be reviewed by its morphological process once again.

In the past, the history of a city can only be understood through scrutiny of the traditional reference and ancient map. Acquiring the precise location and boundary of an urban area is impossible because of the technical limitation of measurement. Therefore, for the purpose of interrelating the social environment, human activity, and physical environment, urban form, the study of the morphological process of an area may be crucial, because the morphological process is one of the practical ways to present urban development in different periods. Furthermore, the identification of the area, presenting a series of morphological region, can help

to clarify the process of urban evolution. Based on these related studies, each accretion of built-up area and the limit of urban extension, so called “*urban fringe belt*”, can be associated with the location and the form complex character by the sequence of urban development. However, to recognise the boundary of these two kinds of region is extremely difficult. Thus, we have an urge to find another instrument to measure the morphogenesis course. With a view to tackling the problems above, in this study, the morphological process of some representative regions will be identified, and the specificity of the character in different period will be analysed.

Tainan, the oldest port city in Taiwan, is located on the East Asia marine trade routes. Since 17th century, the city has been experienced three major events which caused significant urban growth, including the Age of Exploration, industrialisation, and post-war population explosion. Accordingly, these experiences of expansion make Tainan a pertinent case to illustrate the morphological process. Based on the survey of this research, there are three types of built-up area and two kinds of ‘*fringe-belts*’ in Tainan, and each prototype reflects Tainan development history, including the growth of population and human activity, in certain period. This research endeavours to propose an instrument to understand the process of every morphological region, especially in larger scale. Furthermore, this achievement can help to shape the context to design the urban form in the future.

The related research of morphological process and urban form

The related urban morphology theory, mentioned the spatial continuity of the city (Rossi, 1966), represents the evolution of space. Furthermore, chronological character can be left and carved on the urban texture (Conzen, 1985). Because of the continuous process of evolution, the contemporary structure of urban form must contain the condition of the last era (Erith, 2000). According to the implication above, we can infer that the development course of the past shape today's urban form. The following paragraph will reveal the related study of morphological region which is simultaneously made by the evolution of urban and the factors of deformation, or called morphological process.

The evolution of morphological region

The spaces with geographical similarities will become a spatial grouping of form ensembles, which has “*Ganzheit*” character, such as urban core, period accretion, fringe belts, and the redevelopment of commercial centre, within the process of urban development (Conzen, 1977).

From the macroscopic point of view, these morphological regions have their own specific development orders and locations in a city. On the one hand, the built-up area will become broader and denser from the city centre as the number of the population soars (Whitehand, 2001). On the other hand, fringe belt will be generated as the growth of the population slows down. So the long term period of the fringe belt will be begun with low density and unrepresentative building types (Whitehand, 1994). Hence, distinguishing the built-up area and fringe belt by the urban develop density can help us to define the urban core area and the urban edge (Whitehand, 1994).

Figure 1. The comparison between Europe and Asia fringe belt model.

Based on the definition of morphological region in great detail, built-up areas hold the most activities in the urban areas and have building coverage in high density. A city as a container which accommodates the characteristics of the contemporary era and the results of all life (Mumford, 1961). Therefore, the built-up areas, which are established in the early times, are supposed to experience many events, causing deformation process and accumulation. Because of the urban form character of fringe belts, such as rectangular shape, larger average plot size, series of the norm for plots in a housing area, less hard surface and fewer road crossing ... etc. (Whitehand and Morton, 2003), the built-up area and fringe belt can be defined by distinguishing the building coverage rate and street density. Furthermore, identification of the built-up area and the location of the fringe belt can help to us to know the chronological character of morphological region.

Generally, the traces of circled proliferation which were made during the process of development can be easily found in many European cases. However, the rapid development of Asia city results in different trajectories in shaping a city. The character of a space keeps changing. To illustrate this, numerous fringe belt areas are turned into built-up areas because of new development. Therefore, the boundaries of the built-up area and the fringe belt can barely be recognised. Accordingly, current urban form in Asia can hardly represent the boundaries and morphological region of a city in different periods. For the purpose of observing the evolution of Asia cities, we need another approach to substitute for morphological region.

Morphological process

Morphological process, representing the causal sequence of urban deformation, can be used as a tool to measure the sequence of urban development. The morphological process in different periods will be recorded on today's urban texture. Thus, this evidence of deformation can help to reveal the temporal and spatial position of every morphological region. Admittedly, the fringe belt and the built-up area of a city can barely be observe in Asia cities. It is possible to figure out the morphological process by identifying the key factors of morphological process in every region's form complex.

According to the previous European morphology studies, the formative process of the townscape includes three stages: accumulation, adaptation and replacement of forms (Conzen, 1985). In fact the formative process of each area will vary from case to case because of the unique characteristic of every place, and furthermore every area is deformed in different way.

The following paragraphs are the definition of each morphological process in related research:

Accumulation

In general, primary and secondary accumulation in the intensive and extensive morphological process of a city will be happened in the case of evolution of society and culture. Thus, the proliferation of a city can be illustrated by observing the shape and the density of built-up areas.

Adaptation of form

The adaptation of form particularly occurs in existing built-up area. During this process, the built-up area in a city may be reshaped to adapt the functional transformation of a city because of the change of social environment. Therefore, outbuildings, the additional constructions, can be regarded as the indication of the adaptation of form.

Redevelopment of form

The existing urban form is usually divided by the route network, adaptive redevelopment and the extension of the road system. Therefore, parts of the existing built-up area may be removed, reconstructed and reformed.

Based on the related research, every area has distinct the morphological process due to the contextual differences in different regions and different periods (Conzen, 1977). Moreover, the rearrangement of land and building can be revealed in the land investigation. According to this context, the morphological process can be understood as following. Firstly, the accumulation process can be recognised by identifying the additional constructions in a city, because of the difference between building density of primary accumulation and that of secondary accumulation. Secondly, the adaptation process can be observed in the area, which experiences transformation of land-use or building construction. Lastly, the plot integration, the building reconstruction and the change of street system can be regarded as signs of the replacement process. Figure 2 reveals the system of the correlation between the form complex and morphological process. The “step” of every process can be seen in the single or multiple combination of form complex.

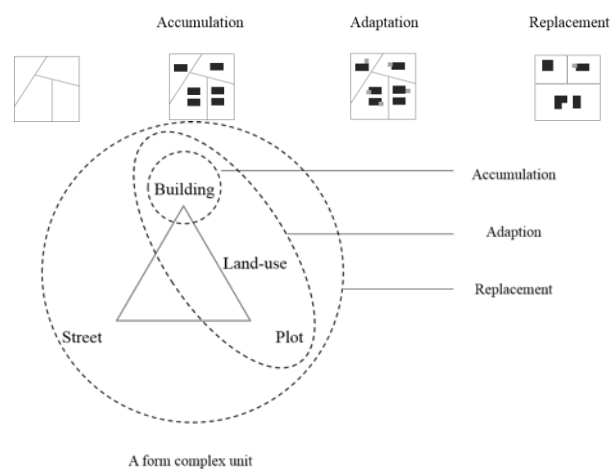

Figure 2. The correspondence between morphological process and form complex

Model

After reviewing the theories of morphological processes, we can apply them to the explanation of deformation sequence of urban form. Morphological regions may have diverse sequence of morphological process because of their different form complex and length of time during development. In most cases, there are three kinds of scenario, which are showed below:

Scenario A: initial accretion

Scenario B: repeating all kinds of process

Scenario C: jumping transformation

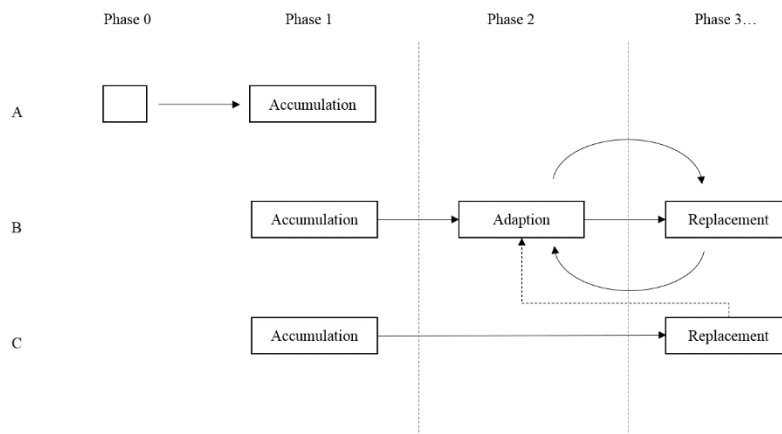

Figure 3. The model of morphological process.

As shown in figure 3, Scenario A is the initial morphogenesis stage which, under the demand from social environment, urges to establish the settlement. This situation can usually be observed in new development area. Scenario B is the most common scenario. After the primary accumulation, the morphological region will start to evolve to adapt new social environment. And after that, due to obvious external factors urging the previous space to change, the space may start its redevelopment process. In this scenario, the adaptation and replacement are in an iterative process. On the other hand, Scenario C is less common and only in case of the rapid growth of population. This situation can be observed through the immediate collage of the urban texture for the living demand. Mostly, in this scenario, the construction works, which are usually large scale or huge amount of residential houses, are determined by the authority. Furthermore, because land ownership generally does not belong to the occupier, there is no right for them to merge the plot or rearrange the land for the buildings which meet the demands in the future. However, the area would change or re-growing when facing the massive demolition, which, therefore, skips the adaptation phase.

However, the scenario can only describes the built-up area in the urban area. For the cases which remain undeveloped status or, in other words, are “fringe belt” (Cozen, 1960) in original stage such as the development of new town may have different morphological process. Although a fringe belt has lower building coverage and social network density, it still maintains the relationship with the urban area and remains the existence urban texture. In order to become a built-up area, fringe belt should go through a significant transformation in order to coordinate the urban area. Therefore, this type of space usually skips accumulation phase, and directly starts from replacement stage.

Figure 4. the Fringe belt morphological process.

Fringe belts have different ways of transformation according to their location and size. For instance, inner-fringe belt or middle-fringe belt which locates between the built-up areas is less likely to have large-scale redevelopment. On the other hand, the outer-fringe belt is usually more flexible to carry on large-scale redevelopment. Therefore, by recognising the existing built-up area which is in accordance to the extent and changing of form complex. Then, by compare to the location, it is able to identify the past fringe belt where might be located. According to the spatial characteristics of the morphological region and the sequence of morphological process, this study will present actual operating procedures and analytical methods to analyse complex urban texture in Asia in the next chapter.

Methodology

Based on the above model, we can understand that we should examine the evolution of the process by identifying features of the built-up area, fringe belt, and the morphological process, which contained in every morphological region. Next, those features can be correlated with the sequence according to the location and specificity period (Conzen, 1988). The following parts are the instructions of the instrument for the measurement of the evolution of the process:

The instructions of the instrument

Because the evolution of the city as a whole should be regarded as a single unit. In order to identify "Ganzheit" character or geographical similarities of morphological region, this study proposes a method from macro perspective to categorise space and explain the regional differences. The method of operation shows as follows:

Step 1: Standardizing the measurement unit

Because area is usually too large to be measured as a single unit and observed in complete 'surface', the method suggests to separate the continuous space by using fishnet system which can help to standardize the observation unit. The area of the smallest unit varies with the size of targeted city. The purpose of separation is to standardize each spatial unit in homogeneous perspective and to reduce the potential errors which may occur in the next stage if there are different sizes of the units.

Figure 5. the illustration of cutting fishnet.

Step 2: Analysing the percentage of street and building coverage per grid

Calculating the building and street coverage area of each unit, which may be the most representative are of the property, can help to find out the built-up areas, fringe belts and rural areas in the city. The building coverage can represent the intensity and density of development; the road coverage area can be regarded as the response of the difference of planning texture and the street level. Revealing both the classification and the overlay is a practical approach to distinguish the different density and development intensity of each areas.

Figure 6. The percentage of the street and building coverage.

Step 3: Defining built-up areas and fringe belts

The following diagram shows the four levels of building coverage and three levels of street coverage. Twelve different combinations can be arranged out by overlaying these characters. In these twelve combinations, both the coverage of built-up area, the ratio of which is lower than fifty percent, and road coverage, the ratio of which lower than twenty percent, are regarded as fringe belt, while the rest combinations have relative high density of built-up area. At this stage, we can identify the boundaries of urban growth and built-up areas in a city.

Step 4: Classifying the morphological region

In this stage, we need to find out the morphological region form these twelve categories, because the space can only be classified by building and street coverage as a criteria to judge heterogeneity in the previous stage, and furthermore that can merely determine the spatial distribution of similar spatial quality, which is not accurate descriptions of each morphological region's "genius loci". Therefore, we have an urge to introduce another approach to identify the prototype of morphological region. As a result, with a view to identifying the morphological process in the next stage, we need to describe the characteristic of each form complex in detail.

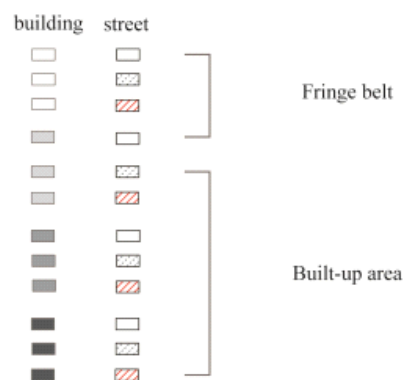

Figure 7. the type of the arrangement.

Step 5: Corresponding to the morphological process

The morphological process, such as accumulation, adaption and redevelopment, in each form complex will be found in this stage. Then, the sequence model of morphological process can be correlated to the phase which each morphological region had experience.

Step 6: Finding out the evolution of urban forms

The morphological evolution sequence of the urban form can be recognised by matching every morphological region and the location of inner, middle and outer fringe belt. In this stage, we can also identify the past fringe belt which becomes to built-up area now. The steps above can help us to find out the sequence of development.

In order to reveal to the characteristics of the periods, we need to seek to another verification to confirm that whether the sequence of development is correct.

Verification

The steps above can help to measure various morphological regions of a city and reveal the processes of urban evolution. In fact the morphogenetic changes of a place can be associated with the character of socio-environment in a certain period of time. To illustrate this, the morphological process of an area usually reflects some significant events, which may be caused by planning programme or political power, such as population growth. For example, the fluctuations in population growth can roughly present the urban transformation of an era; the turning point of the rate of population growth can help to relate the morphological process of an area to the significant event in a period of time. In addition, every related event and planning programme has the announcement date which can be obvious evidence of city deformation. The steps, identified in this research, can help us to find out the evolution of urban form through the morphological region and the morphological process. This result can be applied as a planning method to reshape urban context in the future and rethink planning laws of each region.

Case study

Tainan, the first city in Taiwan, was a part of the East Asia trade route and an important port city in world trade system before 18th century. Over the years, Tainan has experienced many

times of morphological transformation such as the period of modernism construction planning, World War II, post-war population explosion, industrialization and etc. Under this context, the city developed its own way to adapt the environmental change and therefore, created many kinds of morphological region. In the period of post-war population explosion, the population in Tainan had grown from 200000 to approximately 800000. Numerous developments in certain regions sprawl and some inner-fringe belts have been changed into built-up area. Thus, the boundaries of the morphological regions have therefore become indistinct and this situation increased the difficulty to identify the sequence of urban morphological change. To understand the evolution of Tainan urban morphology, this study will try to use the method of morphological process to explore the traces of spatial transformation. The following paragraphs are the results.

Result

We identified the boundary and area of built-up area, fringe belt, and the sequence of morphological region growth by the morphological process measurement. The followings are the results:

The built-up area and fringe belt in Tainan

To find out the current major development area and marginal zone in Tainan, we adapt fishnet system to calculate the building and street coverage for each grid. The area of Tainan metropolitan area is approximately 215 square kilometres. Due to the city's huge scale, this study separates the city into 1800 units and each unit is 500 meters in length and width. Through the calculation we can acquire the percentage of the building and street coverage in each grid. After that, we combine the data with the digital map of Tainan and analyse the distribution of different coverage level. Since there are two variables (street and building coverage) with three and four different levels respectively, there will be twelve categories showed in the map.

In this research, if the unit's building coverage is less than fifty percent and street coverage is less than twenty percent, this unit will be defined as fringe-belt. Hence, there are six categories of fringe-belt and six types of built-up area. However, after identifying the built-up areas and fringe belts in Tainan, we found that the morphological region of Tainan does not comply with the principle, concentric circle model. Therefore, we need another process to identify the space transformation of Tainan.

The morphological region in Tainan

Based on the results of last phase, investigation of the location, building arrangement and land-use type can be accorded with twelve categories. After this process, the morphological region in Tainan can be recognised. As the table 1 shows, four kinds of region have their own spatial particularity. And through the analysis of different spatial characteristics or, in other words, the traces left by the urban transformation, we can identify the possible morphological process of the targeted area. After this stage, we may identify every morphological region and correspond them with the sequence of urban evolution. In addition, we need to correlate the relation location with different morphological regions and therefore the description of the character in each region can be precise.

Table 1. The analysis of morphological region.

type	region	location	Form	Arrangement	Land-use	Process
Type 1 City centre		Urban core	patch	1. organic arrangement 2. fill up the plot	R, R/C	Accumulation, Adaption, Replacement
Type 2 Accretion area_1		1.The extension of core 2.Edge of core	1.patch 2.point	1.Standardized arrangement 2. fill up the plot	R R/C/F	Accumulation, Adaption
Type 3 Accretion area_2		Edge of core	Patch or point	Standardized arrangement	R	Accumulation
Type 4 factory		Urban edge	Patch or point	Big volume tightly arrangement	I, I/R	Accumulation, Adaption

(Land-use code: R- residential, C- commercial, I- industry)

The sequence of morphological region accretion

In order to confirm the chronology of morphological process, this research will compare the current relative location of built-up area and fringe belts. As figure 10 shows, the fringe belts of Tainan are mainly located in outer area.

The inner-fringe belt which as used to be the city walls is not easy to be observed. The middle fringe belts have higher building coverage, but they lose their urban pattern as well as the linkage between patches. The outer fringe belts have lower building density, while remain the linkages between the patches which surround the existing urban area.

The following step is the comparison of location and distribution between fringe belt and built-up area. Figure 10 shows that the accretion spaces are mainly located between the urban core and middle fringe belt, and some of them are merged into the fringe belt. By inference, this could be the evidence of the transformation from fringe belt to built-up area. This kind of space usually contains the traces of large scale redevelopment which aims to the contemporary demands.

The comparison between Asia and Europe urban form

Based on the results above, this sector endeavours to compare the cases in Tainan and United Kingdom. The formation processes of built-up area between these two cases are relative similar. However, the fringe belt of cities in Tainan and United Kingdom is quite different from European's patterns. Although there were numerous city walls in Tainan in the past, most city are torn down now because of the soaring number of population. As a result, the boundaries in the past has been cleared and filled up by the new buildings. The exact place of inner fringe belt can barely be identified; thus the pattern in Taiwan is quite different form the British case which has the inner fringe belt, a closing type.

Figure 9. The analysis of building and street coverage.

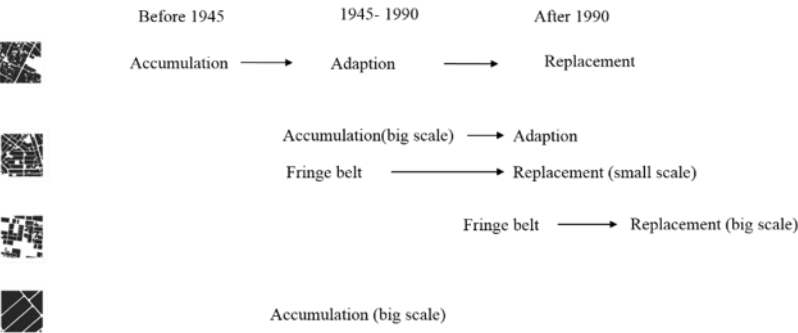

Figure 10. Morphological region and morphological process.

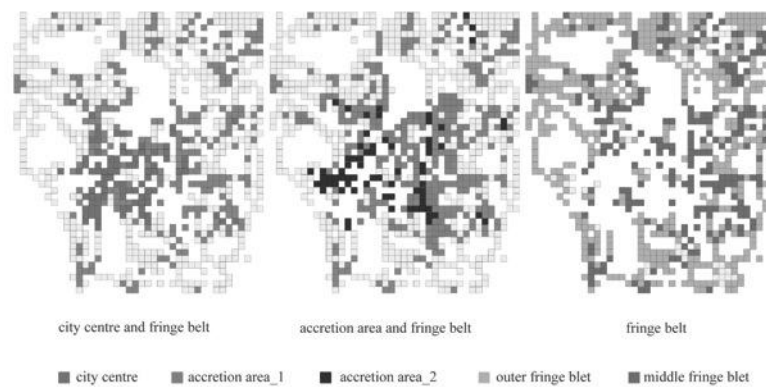

Figure 11. The distribution of fringe belt and built-up area.

In addition, the middle fringe belts of these two cases are also quite different. In Tainan, most of the middle fringe belts may be converted into built-up area in the period of rapid population expansion. Now we can only observe the segments left over from the built-up area. The outer fringe belts in Taiwan are likely surrounded by the city development area, while European cities usually have opened outer fringe belts.

The differences above elaborate the particularity of Asia and Europe, and these discrepancies between cases result in the different morphological region and pattern. However, the trace of development can still be observed in nowadays urban form by the indication of the instrument of morphological process.

Table 2. Comparison of fringe belt between British and Taiwan.

Type of fringe belt	British	Taiwan
Inner fringe belt	Close fringe belt Surrounding the kernel of a town asymmetrically Antecedent fixation line	Only for the city with walls. After removal of the wall, through the conversion process, may not become a closed ring shape.
Middle fringe belt	Open fringe belt Residential integuments	Open fringe belt residential-based, mix with commercial use
Outer fringe belt	Open fringe belt Current periphery of a town	Open fringe belt Current periphery of a town
Factory fringe belt	--	Open fringe belt Surrounding the factory district mix with residential and farm land

Conclusion

In this study, for the purpose of analysing the complex shape, which is curved in particular chronology in East Asia, a new method has been proposed. The past studies have shown that a group of built-up area, sharing similar character, may be constructed in a certain era and the fringe belts of that expand outward in a concentric-circles way. In the rapid expansion of housing and the great demand of economic development, the fringe belt in the inner location is often transformed into built-up area by filling up the buildings or a large-scale replacement. These developments erase the trace of the edge of urban growth. Because the formation trace is

always recorded on every form complex, the morphological process, representing the cause and event in the formation, can be the instrument to measure the significances of urban formation.

The methodology for analysing the formation of urban form is established by this study. The following steps can roughly present the whole process of this method, including standardising the observation unit, determining the edge and built-up area, and finally identifying the morphological process to correspond to the morphological region and develop sequence. While, this method can also be adjusted by the different scale of observation area. The oldest city in Taiwan, Tainan is the operation case in this study. The result shows the applicability of this method in detecting the past formation traces in a relative complex urban form. In addition, this method also can be used in observing the relation between the morphological region and the chorology character.

The method, proposed by this research, can be adopted as an instrument to reveal the chronology character of every city, and further shape the context of the urban form in the future. However, this approach measures every city from the macroscopic scale of view, and therefore is not able to detect the subtle change of urban transformation. In addition, the pattern of land-use and the value of categories vary from city to city. Therefore, the method for analysing urban morphological transformation should be emphasized more on the experience of East Asia city development in different scales and the land-use pattern in the future.

The evolution of urban form since post-war period in Taiwan – a case study of Yonghe city

Chih-Hung Chen, Chia-Hua Tsai

Department of Urban Planning, National Cheng Kung University.

E-mail: chihhungchen@mail.ncku.edu.tw.

Abstract. *To reorganize the living environment ruined by WWII, post-war modernism arose with emphasis on quantity and function of residential buildings, which became the mainstream of urban reconstruction. Moreover, the concept “Automobile dependency” (Reichow, 1959) was comprehensively applied in 1950s. Both essential causes led to specificity of urban forms: an observable morphological period (Conzen, 1960, 1985). In contrast to Europe, two different factors, namely industrialization and promptly increased immigration happened in East Asian metropolises, which resulted in the short supply for residential demand. For the causes above, the process of morphological change transformed rapidly that the form changing can be observed evidently. A city is composed of the complexity of “fatti urbani” (Rossi, 1966) and plots (Tarbatt, 2012). These visible and invisible parts are basic units of urban development (Alexander, 1979). By comparing the correlation between streets, buildings and plots, the result of the evolution of urban form since post-war period can be found in Yonghe, locating in the surrounding area of Taipei, the capital of Taiwan.*

Key Words: *morphological period, post-war modernism, urban form evolution, morphological process, specificity of urban form in Taiwan*

Introduction

In recent decades, urban form study has been extensively used for understanding the context of cities in several countries. Among them, the study of urban form for descriptive and explanatory purposes, with the aim of exploring the evolution of urban form (Moudon, 1997) is one of the most essential part.

However, the total value of an urban form evolution could only grasped in its historical dimension. (Muratori, 1959) In addition, any period creates distinctive forms would suit the particular historical dimension. Therefore, the evolution of urban form, which has its causal sequence, can be easily observed through different periods.

In the period after WWII, post-war modernism arose with emphasis on quantity and function of residential buildings, which became the mainstream of urban reconstruction and affect the evolution of urban form in the following decades. Much research has been discussed through this period in western countries while rarely in eastern countries.

Due to the factors above, this present paper tries to explore the evolution of urban form since post-war period in Taiwan in order to find out the specific morphological process (Conzen, 1977) which leads to different evolution of urban form from western countries.

Evolution of urban form since the post-war period

Every city has its own morphological process (Conzen, 1977), and any period which creates particular forms has its morphological period (Conzen, 1960). However, it is the different context makes the evolution of urban form so distinctive in every single country.

Statement of evolution of urban form

Morphological process

Morphological process is any causal sequence that leads to the definition or alteration of any townscape features and their mutual composition (Conzen, 1977). Understanding the morphological process of the cities is the essential keys to know the cities. There are visible and invisible context which influence the evolution of city. However, urban form, which is easily observable, can be understood historically since the elements which it is comprised undergo continuous transformation and replacement (Moudon, 1997).

Morphological period: specificity of urban form

In morphological process, there are series of periods in an area which creates distinctive material forms in the cultural landscape to suit the particular socio-economic needs of its society (Conzen, 1960). When under the different period of historical or cultural context, the invisible facts such as urban planning, policy or major construction project, would reflect on the specificity of urban form. Therefore, by knowing the relation between periods and forms can we know the morphological period in certain area.

The spiral: evolution of urban form

When the forces caused by the historical and cultural context at play, they would have the capacity to change the previous forms into other forms in the circulation of growth and decline. Hence, each circulation represents one specific form based on one specific period. In the trend of urban development, the circulations of specificity of urban form based on morphological period are connected one after another and eventually become a spiral. Morphological process is the continuously rotating spiral, with growths and declines in each circulation. By knowing each circulation and the force influencing the circulation from growth to decline, the casual sequence of the evolution of urban form could be clearly recognized.

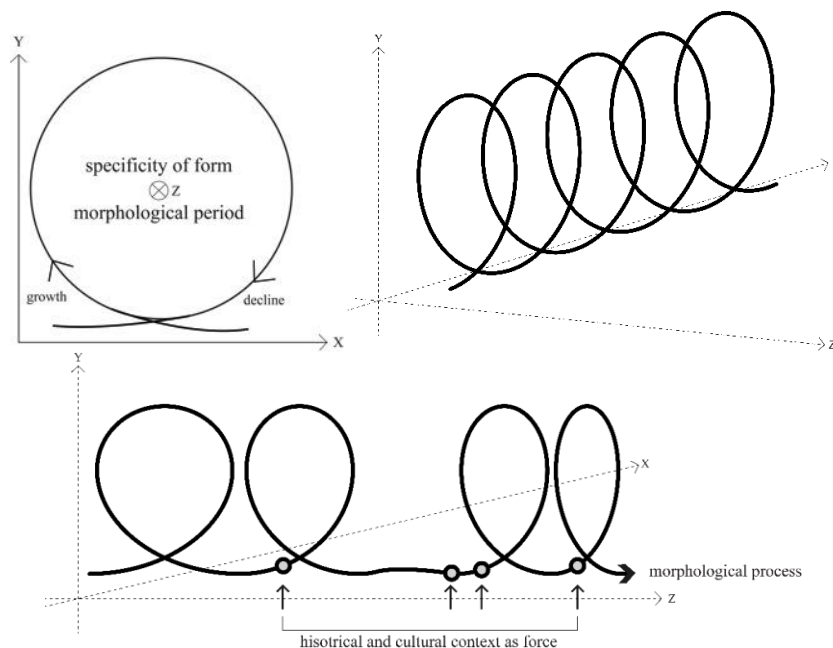

Figure 1. The spiral: evolution of urban form.

Post-war period: “Renaissance of modernism”

In 1950s, post-war modernism arose with Athens Charter to be the mainstream of urban renewal, and therefore influence the urban development throughout the world (Chen & Lai, 2010). In eastern countries, most of the cities weren't seriously destroyed by wars. However, as the colonies of the western countries, the trend of urban planning in western countries greatly influenced the urban form of eastern countries.

In addition, the main idea of post-war modernism still has great impact on the urban landscape nowadays or even in the future (Edward, 1998). Therefore, it is essential to explore the urban development through this specific period, post-war period.

Post-war modernism

The United States played an important role in the modernism movement concerning new advanced building and construction technologies. However, Frank Lloyd Wright was a cornerstone of modernism (Cleary, Levine, Marefat, Pfeiffer & Siry, 2009). His main idea of the architecture, organic architecture with low density of development, was of significance to the following urban planning in America, and so did the urban planning in Taiwan during post-war period.

Zoning: Automobile dependence urban planning

Since the concept “Automobile design urban planning” is comprehensively applied (Reichow, 1959), the idea of zoning came out which led to the different urban landscape from the past. The organic urban fabric is cut by roads and traffic forcibly, which caused not only shattered buildings and plots, but created better location for mix-used or commercial uses beside the street.

Approach to post-war period in Taiwan

In 1949, Nationalist government fled from Mainland China to Taiwan. As the ally of the United States during the Cold War, ROC officials received U.S. Aid, such as military, financial and humanitarian assistance from the United States to their island bastion during 1951 to 1965 (Pellegrin, 2005). And also because of the U.S aid, came out the first government official of urban planning which learned the specialty of urban planning from America (Liao, 2013). In addition, with the extensively used automobile design urban planning, the development of urban planning in post-war period in Taiwan was greatly influenced by western countries.

Methodology

Urban planning is the crucial fact of influencing the urban form, because it has legal effect upon land use, city plans roads, building coverage ratio, etc. Among them, the city plans roads divide cities into blocks and focus on making the regulation of the content in blocks, such as plots and buildings. These visible and invisible parts are the basic unit of the urban form. The paper would focus mainly on the two and also the correlation in between.

Urban planning

Based on the urban planning law in Taiwan, an urban plan shall refer to a planned development for significant facilities concerning urban living, hence it has big influence on the development

of urban forms. And in urban planning, city plans roads are the most directly observable results of the urban planning and they divided cities into blocks.

Not matter the content of blocks, such as plots and buildings, can vary considerably in shape and size, it should develop according to the configuration of streets. And rules in urban planning normally use blocks as the unit to control the development of urban area. Therefore, this paper would use block, which is divided by city plans roads, as the study unit.

Plots & time

In spite of the fact that plot is the invisible element of urban form, it's the basic unit as the urban development (Tarbatt, 2012). And because of the macro-processes have driven changes in urban morphology, the integrity of traditional urban forms would impact on the plot (Tarbatt, 2012). Therefore, by observing the plots, the evolution of cities can be easily seen.

Density is also a crucial part for understanding the series of plots. Normally in historical tendency, larger parcels are subdivided into smaller ones for generating a fascinating or character-full patchwork of form in old cities (Kostof, S., 1991). As the time goes by, street buildings are lost and plots turn larger by combining them together. This phenomenon cause the following landscape: monoculture of land use, monolithic building forms and segregated communities (Tarbatt, 2012), which happened evidently in post-war.

However, the time of urban planning does not correspond to the time of the division of plots in the same place. Moreover, they are under two separate management institution. These lead to the difference between lines of blocks and the lines of plots beside the city plans roads, which causes fragmented area when these two plans overlay with each other. And this paper would exclude those area to reduce the study error.

Buildings & time

A city is composed of the complexity of "fatti urbani" (Rossi, 1966). The city was seen as a material artefact, a man-made object built over time and retaining the traces of time, even if in a discontinuous way (Rossi, 1966). Building is the visible part in urban form and is the main element for directly observing the landscape at present time. In addition, it can also be regard as the proof for the historical events.

Density is also an important part for understanding the development of buildings. Normally, because of the good location of the city centre, it has great potential of development which causes high density of the buildings; while the landscape of suburb area may be low density of buildings.

However, the city has always been characterized largely by the individual dwelling (Rossi, 1966). Because the buildings of residential district change with time and it can be clearly observed, the form of changing can be easily tell. Therefore, this paper would take residential district as the first priority to find out the evolution of urban form.

Correlation between plots and buildings

The plot is an increment of landholding, set out for the express purpose of building, which means the invisible plots would directly influence the visible buildings (Tarbatt, 2012).

Density of plots means the quantity of plots in per unit, which can deduce the ratio of the size in the plot. If the density of the plots are high, there are many plots in per unit and the average of the size in the plot is small; if the density of the plots are low, there are not much of plots in per unit and the average of the size in the plot is much bigger.

Buildings are also same as the inference above. If the density of the buildings is high, there are many buildings in per unit and the average of the size in the building is small; if the density of the buildings is low, there are not much of buildings in per unit and the average of the size in the building is much bigger.

However, in reality, buildings does not correspond to the plots, mostly because of the difficulties of combing the plots to create the new buildings. Hence, normally, we can still see the remaining traces toward plots. In conclusion, the comparison between the density of plots and the density of buildings is worth discussing.

Model of the correlation between plots and buildings

Based on the tendency of the history, the correlation between plots and buildings can reflect the period of time. In the beginning of the development, there are only farms and some built-up area. At that time, farm is people's property and can also be regard as the big plots. Therefore, the density of buildings (BD) is higher than the density of plots (PD), as area A in Figure 2.

As the times go by, there is a tendency for larger plots to be subdivided into smaller ones as the supply of land decreases and demand for it increases (Kostof, S., 1991). The process will go from $PD=BD$ (area B in Figure 2) to $PD>BD$ (area C in Figure 2). In the process B, the plots are mostly equal to the buildings, because the development is based on the urban planning. Later on in process C, the reconstruction of buildings and the construction of widening city plans roads begins in the area which has high potential to develop. And because of the difficulties of combing the plots for new uses, the phenomenon results in many shattered plots, which is the reason why it has higher density of plots than buildings in such area. On the other hand, still some places combine the plots before starting the development. And this will be likely to appear in area A, B or C.

Figure 2. The correlation between plots and buildings.

The correlation between plots and buildings in urban area can be concluded as follows (Figure 2):

A. $PD < BD$

The density of the buildings is high while the density of the plots is low, which means plots and buildings have low correlation. In conclusion, there are larger plots but smaller size of building, which shows that one single plot may have many buildings on it. This categories can be concluded as two: (1) The beginning of the built-up area: Normally, all cities will start at this phase and there are only farms with some farmhouses, or the small area of built up area; (2) Low density of both plots and buildings: At the time goes by, small plots are combined to establish new development and this may also lead to larger density of buildings than plots.

B. $PD = BD$

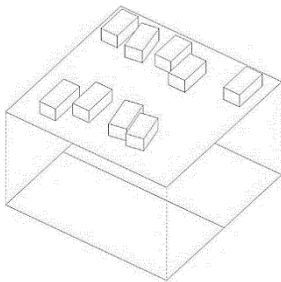

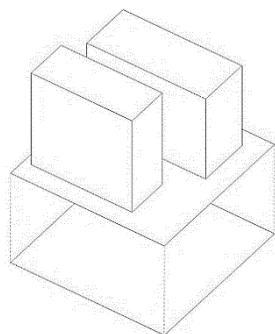

There are mostly same amount of quantity between plots and buildings, which means plots and buildings have high correlation. This categories can be conclude as two: (1) High density of both plots and buildings: The area develops mostly based on the urban planning. There are

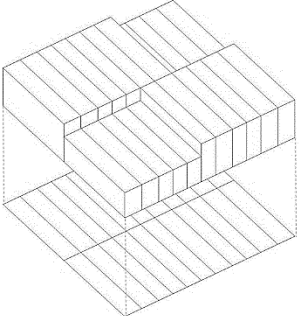

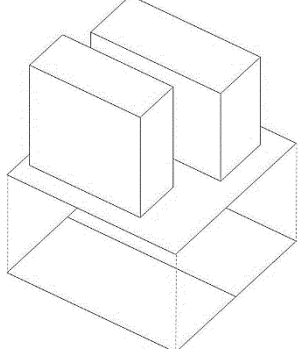

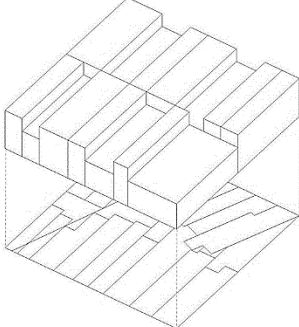

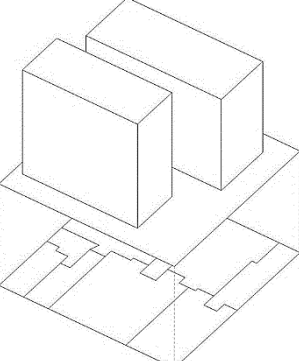

smaller plots and smaller size of buildings, which largely occurred in older period of time; (2) Low density of both plots and buildings: The area develops after the combination of the plots. There are bigger plots and bigger size of buildings, which largely occurred in much closer period of time.

C. PD>BD

The density of the buildings is low while the density of the plots is high, which means plots and buildings have low correlation. In conclusion, there are smaller plots but larger size of building, which shows that there are many plots but just less of buildings on them. This categories can be conclude as two: (1) High density of both plots and buildings: Most are located near the transportation system or the main street. Because of its good location, the area keeps reconstructing but without arranging the plots, which causes the high density of plots; (2) Low density of both plots and buildings: Normally, the area develops on big blocks which is far from the main street and the city centre. Small plots are combined to establish new development and this may also lead to larger density of plots than buildings.

A case study of Yonghe city

Location

Yonghe District is an inner city district in the southern part of New Taipei, Taiwan. It is the smallest district in New Taipei City but the density of the population is the highest in Taiwan.

Figure 3. Location of Yonghe city.

History

The process of urbanization is often accompanied by migration. Nationalist government moved to Taipei in 1949, which led to the migrated population and military dependents' village in Taiwan.

Moreover, because the policy of being air-raid place in 1954 and the first urban planning of Yonghe in 1955, Yonghe city suddenly burst into large amount of people.

In 1951~1965, U. S. Aid happened in Taiwan, which affected the construction of cities, economics or even military event. In addition, scholars brought back the urban planning theories from America, which led to similar ideals of urban planning between Taiwan and America at that time. And the first urban planning in 1957 is based on the ideal of organic and low density of development from America.

Later on after the year of 1970, the population of Yonghe city kept growing because of the migration of town and country. Yonghe was deemed the new residential area for overflowed population from Taipei, and the transition between city and rural area until now.

Figure 4. History of Yonghe city.

Model of the correlation between plots and buildings in Yonghe city

Based on the urban planning of Yonghe city, we find out our study area by using the blocks and land use of residential. And by dividing the density of plots and the density of buildings, the correlations between plots and buildings can be concluded as $PD < BD$ (grey area in Figure 5), $PD = BD$ (deep grey area in Figure 5) and $PD > BD$ (black area in Figure 5):

A. $PD < BD$

1. Because of the population grew rapidly in Yonghe, the density of the development was high in all area. Therefore there weren't place like I1 in nowadays.

1-1 It can be regard as the transitional belt, containing both new and old buildings which remains from military dependents' village.

2. New development with big plots with far location from the centre of the Yonghe city. And the land use is mix-used.

B. $PD=BD$

1. The area develops based on the urban planning. There are smaller plots and smaller size of building with accomplished roads in it. And all area is residential uses.

2. There isn't any area like II2 in Yonghe, which reveals the arrangement of the plots is hard to fully correspond to the new development of the buildings.

C. $PD>BD$

1. The area is located beside the main street and the MRT station, which is the highly profitable area with residential uses and a variety of commercial uses in the first floor in Yonghe. And this phenomenon leads to frequent reconstruction which causes more complicated plots.

2. New development with big plots with distance from the centre of the Yonghe city. And the land use is mix-used.

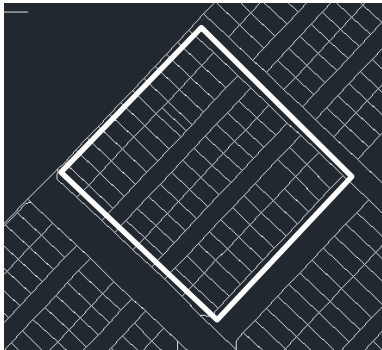

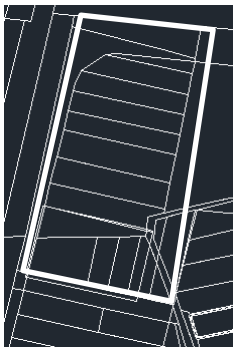

Figure 5. The urban planning of Yonghe city.

Evolution of urban form in Yonghe city

As a conclusion based on the history of Yonghe, morphological period is caused by the historical and cultural context as force. In Yonghe city, there were four main force: migration from Nationalist government in 1949, being assigned as air-raid place in 1954, the first urban planning in 1955 and the migration of town and country. And as the result of correlation between plots and buildings, the specificity of urban form can be classified as: type A1, A1-1, B1, C1 and C2.

By corresponding the morphological period to the specificity of urban form, comes out the spiral of evolution of urban form in Yonghe city. Before the post-war period, Yonghe only has some built-up area and farms on big plots which belongs to type A. Later on, migration from nationalist government occurred and military dependents' village appears. And because the land belongs to government, it still a big plots, hence type also belongs to A. However, this type no longer exists nowadays.

Before coming to the next morphological period, there is a transition of new and old, type A1-1, which under different time of reconstruction in one certain block. Next, because of being assigned as air-raid place in 1954 and the first urban planning in 1955, Yonghe city suddenly burst into people, and led to reconstruction of buildings, which is type B1 and type C1. In spite the fact that they belongs to same period, the type is so different due to the location and the automobile design urban planning. As the result, the arrangement of plots and buildings is complicated if located in the centre of Yonghe city, while it's in order if it's far from the centre. At last, in 1970s, the migration of town and country happened, and the high rise buildings appear, which may belong to type A2 and C2.

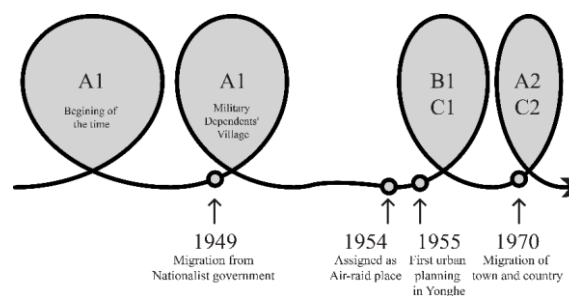

Figure 7. The spiral: evolution of urban form in Yonghe city.

Conclusion

Model

Every city has its own morphological process, and any period which creates particular forms has its morphological period. However, because of the different context, the specificity of urban form makes the evolution of urban form so distinctive in every single country.

From this paper, we can know the specificity of urban form from the correlation of the density of plots and the density of buildings. In conclusion, the process of the specificity of urban form begins from area A, which is greatly affected by the idea of modernism in America. However, because of the large amount of people cases by nationalist government and country to city, it goes on to B and C, and then may go back to type A at last, which is totally different from the idea of the low development of the first urban planning in 1957.

Based on the historical and cultural context as force, the specificity of urban form can correspond to the morphological period. And as the time goes by, the circulation of specificity of urban form and morphological period is like a spiral, which can represent the evolution of urban form.

Figure 8. The correlation between plots and buildings in Yonghe City.

Recommendation for future work

However, there are some issues coming out when doing the research. Following are the issues which can be considered in the future:

- 1) There may be heterogeneity in one certain block in Yonghe City:

By using the density of plots and buildings, the content of the inside block will be regarded as homogeneity. However, the different arrangement may be the factor of influencing the evolution of urban form.

- 2) Types may be disappeared through time:

As the type A, it once appeared in the past, but because of the fast regeneration of urban space, it turned into other type. Therefore, it may be possible that some other types are not be discussed.

Analysis of the correlated relations between ancient Chinese urban morphology and social culture

Jinghua Dai, Zhu Wang

College of Civil Engineering and Architecture, Zhejiang University

E-mail: jinghuadq@gmail.com

Abstract. *Cities gestate culture. Different cultural backgrounds and ideological concept promote diverse city planning thoughts, as well as various forms of cities. Nowadays, the development status of Chinese city, such as the high speed of construction along with the resulting "one side thousand cities" pattern, urges the designers to turn over to think the guiding ideology and practice way of future city construction. However, when looking back upon ancient Chinese urban morphology, its distinct features of the age and spatial attributes are worthy of deep consideration. Based on spatial distribution of ancient cities, this paper takes ancient Chinese culture as an entry point from three cultural levels including the system, material and spirit. Furthermore, the effect and influence of culture on constructing urban form are explored and analysed, and then cultural connotation of ancient Chinese urban morphology is summarized aimed at leading the future urban to be constructed with distinctive character and sense of belonging.*

Key Words: Ancient Chinese, urban morphology, system, Ancient Culture

Introduction

A well-known western scholar Lewis Mumford has a famous metaphor, city is a magnet and a container, which respectively represents city's spiritual essence and physical form and he claimed 'the magnet comes before the container'. He also thought 'If the great capitals, like Babylon, Rome, Athens, Baghdad, Peking, Paris, and London, have dominated the history of their respective countries, it is because they were capable of representing and passing on a larger portion of their total culture.' It can be found that culture has significant influence on urban planning. As a 'magnet', different cultures make cities different in manners and customs, and linguistic performances as well as architectural style and urban morphology.

During the form and evolution of ancient cities in China, cultural conception has great formative effects and it's also an important and unique property of a city. Cultures that greatly influences ancient city planning in China can be classed into three fields: firstly forming and culture of the well-field system, secondly the architectural culture of wooden frame and city layout of ethical topic, and thirdly Chinese traditional theory that man is an integral part of nature, Zhouyi and geomancy, which respectively correspond to system cultural, material cultural, spiritual cultural 3 layers in Leslie A White's theory about structure of urban culture. All the above three fields together constitute an intact theory system that influences ancient city planning in China.

System culture level—the well-field system

As the mediating structure of urban culture, system culture is its normalization and institutionalization. The transition of urban culture will be reflected by vicissitudes of various systems. Urban system culture is based on material culture and mainly aimed at meeting more essential needs of urban inhabitants. And the need produced when citizens try to deal with relationships between individuals or between individual and group because of their

communication needs. Among system culture, family system, economic system and political system are the most predominant. Economic system has the greatest influence on urban morphology while it determines the political system.

China is a large agricultural nation and agriculture is the most important material production department in feudal society, which is also main source of taxes and land rent. The tendency of stressing agriculture and restraining commerce was established in Zhou dynasty and developed through the whole feudal society. To some extent, the early urban morphology in China had been affected by the farming system represented by the well-field system. And the well-field system is a Chinese land distribution method, which means the “nine squares” system(of land ownership in China's slave society) with one large square divided into 9 small ones, the 8 outer ones being allocated to serfs who had to cultivate the central one for the serf owner. This system promoted the feature of square grid of Chinese ancient cities. A book named research on Kao Gong Ji's record on pre-Qin Period city planning system has described that city can be viewed as a large shaft area, whose crisscross footpaths between fields consist road network of cities, and some identically-sized square field are utilized as urban construction lands according to the well-field system. Therefore, the overall spatial layout of square grid of Chinese ancient cities was established. A famous Chinese ancient book "Kao Gong Ji artisan" has detailedly described the basic city planning based on the idea of the well-field system. And the Imperial City has the following characteristics:

Figure 1. Imperial City described in Kao Gong Ji artisan.

1) The ancestral temple of a ruling house is located on the left and Altar of Land and Grain on the right of the Royal Palace while imperial courts are on the front and markets behind it.—It is a key feature of the planning and structure of the Royal Palace. This feature not only determines the location of central district given priority to body with palaces but also lays the foundations of the overall building planning, which fully embodies the main idea of royal dignity. Palaces are required to be built in the center position of whole city and around it the ancestral temple of a ruling house, Altar of Land and Grain, imperial court, and markets are located of bilateral symmetry. The central axis in North-south direction of palaces is chosen as the principal axis of urban planning, along which three imperial courts symbolizing the state power are built successively to strengthen leading role. So, controlled by the central axis, the ancestral temple of a ruling house and Altar of Land and Grain representing the social rites are unified to form the central district with the Royal Palace as its center. This is palace area and it's the main part of planning and structure of the whole city. And other urban parts are arranged to be located

around it in accordance with their respective functions and layout requirements to together constitute an organic integrity.

2) The regional division is clear and the land layout is rigorous for the Imperial City in respect to each individual component function of the whole planning and structure. The palace area is located along the central axis of whole city planning while other parts around it and of small-scale, which sufficiently demonstrates that the palace area is the emperor's political castle. Industrialists and businessmen live near the market and princes and aristocrats near the palace. However, the common people have to live in the four corners of the city. This structure is formed completely based on the feudal etiquette and it also shows an attribute of the Imperial City.

3) A system of roads consisting of many horizontal roads and axial routes is founded, where there are three main roads, some secondary main roads parallel to the east-west direction or the north-south direction, and also circumferential roads around the city. The road network is symmetrical distributed around the center district while the two middlemost main roads are respectively symmetry axes vertically and horizontally and their crossing point is the palace area. Meanwhile, the main roads extend directly to the city gate so that they are able to connect to roads outside the city. In this way, the system of roads not only helps every parts inside the Imperial City connect to the outside worlds, but also strengthens the reign of the emperor.

Therefore, following the ritual concept, the construction system established in Zhou dynasty utilized the seniors and juniors idea represented by different orientations to locate different functional architectures. A kind of logic about urban planning was gradually formed and it was a ritual planning rule. And the layout centered on the palace district. Firstly, this layout showed slaveholders' sovereign power and dignity and at the same time it's convenient to meet their needs to rule. Secondly, Zhou dynasty adopted the architectural style of square grids in the well-field system and made vertical and horizontal roads compose a strong network. Overall, this architectural conception played a significant role in forming of the size, layout, roads and structure of a city. Especially the urban land-use planning system built based on the well-field system produced far-reaching effect to improvement of ancient city planning in China. And it was inherited by later generations and also developed into a traditional city planning method in China.

Material culture level

Material culture in cities consists of a variety of perceptible and physical infrastructures. The reason why these physical things are incorporated into the scope of urban culture is that not only they embodies the humanized nature feature but also they are the most direct-viewing and most vivid representation of urban culture. It is in the sense of, Kevin Lynch points out, city culture material, is a communication medium, and shows a clear and ambiguous symbol. As one of the most direct expressions of urban culture, architectures directly influence the forming of urban morphology.

Architectural culture about timber construction

The influences traditional architectural culture had on ancient urban planning was firstly reflected in that every layout planning, fortification material and construction technique greatly affects square city walls and square grid of roads. Because of the particular climate, architectures were generally built facing the south and with the north at their back, and on the sun-facing side and the lee side. It gradually led to the north-south square grid of roads network (figure 2). Secondly, nearly every building, such as houses, gardens, palace and even entire city, in ancient cities is surrounded by walls. This courtyard wall culture naturally formed a square and closed architectural feature and the square and linear city construction style therefore became more convenient. Thirdly, the group buildings layout method mainly consisting of

timber construction had a more profound effect on urban morphology. Timber constructions were chosen by everyone from the emperor to common people since that on one hand it was flexible for timber buildings to stretch on planes and multiple buildings could be arranged of axial symmetry in space on the other hand.

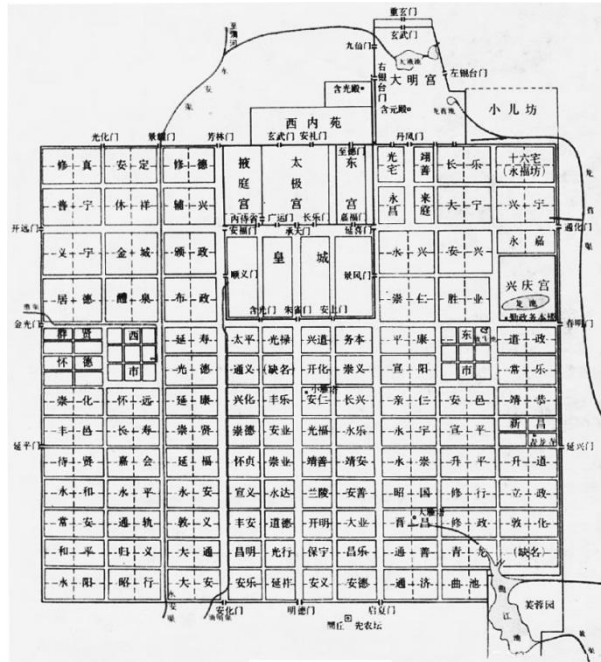

Figure 2. Layout of Chang' an City of the Sui-Tang Times.

City layout with a pecking order and a theme on politics and ethics

Spatial layout of ancient cities in China corresponded to hierarchical feudal ethics culture, which showed supreme power of the feudal society closely monitored the social space. In ancient urban planning and design in China, square form and central position are welcome and favored, and urban space arranged according to quadrangles and alleys had distinct levels and close-knit construction. Chinese famous scholar Xiaoxie Zheng thinks that there was always a kind of square basis largely identical but with minor differences running through spatial distribution and organization of ancient cities in China. Buildings of different functions were often arranged according to obvious central axis so that cities and groups of buildings were constructed on the basis of certain rules and systems. Paratactic banks of quadrangle dwellings composed streets and alleys, which, well-regulated assembled, further composed quadrate or anomalous cities surrounded by defensive walls. From an urban perspective, you can pace up and down from streets hutongs and lanes gradually to courtyards and houses while, as a resident, you could walk out of the room and go to courtyards, lanes and streets and even the outer world. Entire city showed a perfect rationality and a methodical order. Traditional Chinese cities with the artistic methods of organizing urban system and arranging urban layout synthetically reflected political institutions and ethical cultural features in a feudal centralized country.

Ancient Beijing (Peking) couldn't be a better example. The Forbidden City had been always located in the center of Peking until Qing Dynasty was overthrown and it coincided with the north-south central axis of Peking. As a representative of social rites leading urban construction, architectural construction and distribution in Peking were symmetrical and tight. Hall of Supreme Harmony was located on the center of central axis and Temple of Heaven and Earth respectively on its south and north as well as Altar of the Sun and the Moon on east and west

(figure 3). Qing Dynasty had stringent regulations on construction of cities of different classes and scales, materials and colors of dwelling houses of different official titles. For example, the number of housings for officials was given a clear definition based on level of their positions. Also, the seniors and juniors idea was reflected in design and construction of traditional quadrangle dwellings in China, which were thought as city cells. For quadrangle dwellings, the head of a family lived in principal room facing south, the eldest son in west-wing room and the servants in outer court following the pecking order.

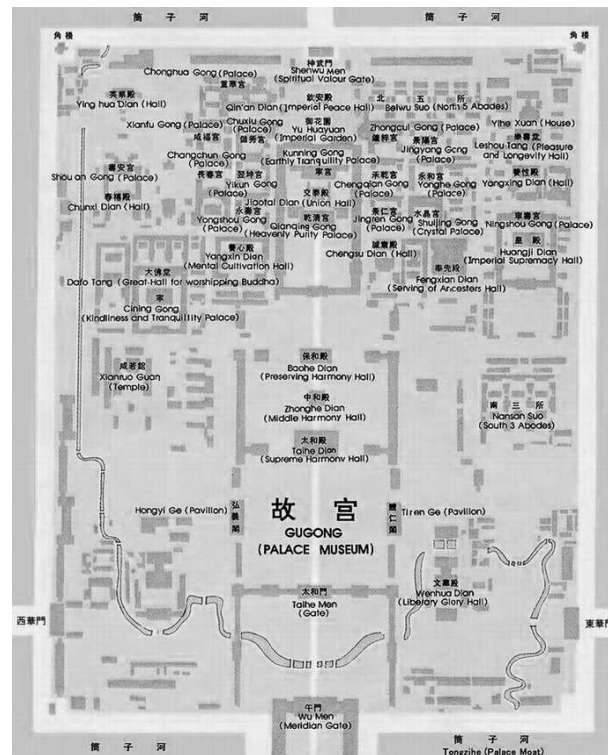

Figure 3. Layout of Forbidden City in the Qing Times.

Spiritual culture level

Confucianism-- theory that man is an integral part of nature

Cities are built on the basis of natural environment, so layout structure and overall appearance of every city will be influenced and restricted by geographical environment and natural conditions. In addition, all buildings in a city are also a kind of environment, where people engage in a variety of activities and which therefore is known as space art.

When ancient Chinese designed and constructed urban architectures, they paid much attention to harmony between buildings and surrounding environments. By means of unifying urban planning and design and combining with the nature closely, they tried to create a pleasant urban ecological environment, which is closely related to Chinese traditional ideology and culture. In dealing with relationship between human and nature, Confucianism advocated the idea that man is an integral part of nature, 'The wise man delights in water and the good man delights in mountains', insisting the organic integration of man and nature. Taoism emphasized 'calm and content himself of nature', 'Man law the law of the heavens, France Road, Imitation of Nature'. Additionally, geomantic omen that highlighted yin-yang and five elements was also supplied to ancient architectures in China. Although it contained a little of superstition, its

purpose was to find a fittest living place for human beings based on mountains, rivers and other natural conditions. It was also supposed to realize harmony between people and nature and in this meaning it was interlinked with the idea of Confucianism and Taoism. This view that we should learn from law of nature was given creative range in site selection and planning of Chinese city, structure and modelling of architectures and especially construction of landscape garden.

In site selection of a city, ancient Chinese laid stress on harmony among the heaven, earth and man to find a suitable living environment. During the overall arrangement period, Chinese cities were mostly constructed suiting local conditions and coordinated with nature. And cities with distinctive style were developed relying on surrounding environment. For instance, Suzhou is a beautiful city where artificial and natural rivers and other resources are adequately utilized to found a waterborne and land transport network (fig 4). Although, for about two thousand years, Suzhou was destroyed and rebuilt many times, its construction still comes down in one continuous line and changes little.

In planning for groups of buildings, Chinese traditional city builders were good at utilizing mountains and rivers to create a good environment architectures and nature integrated. Taking Slender West Lake as an example, many gardens are built along the lake, realizing that artificial and natural environment are combined, and delectable scenic beauty is presented. For thousand years or more, following nature and utilizing mountains and rivers, Chinese have built countless cities that are coordinated with nature. It is a kind of cultural creation as well and one of the basic contents of Chinese culture about traditional cities.

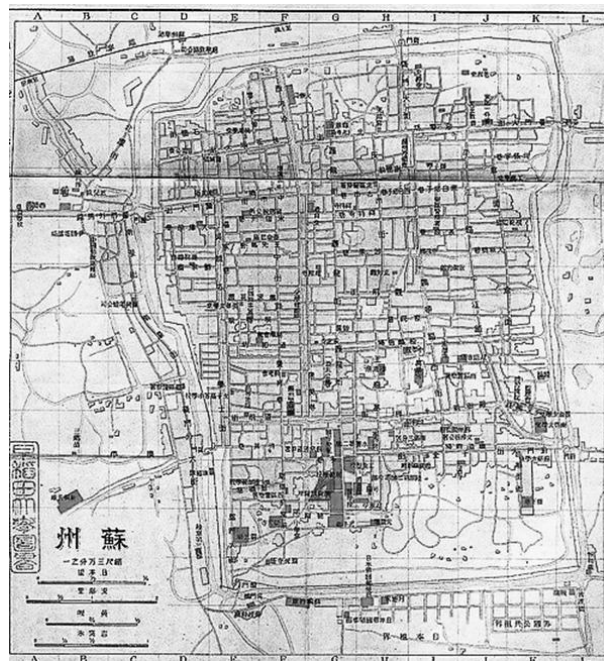

Figure 4. Layout of the ancient Suzhou city.

Taoism--yin-yang and five elements and Zhou Yi

Gemmu of Chinese culture—Zhou Yi is thought as a holy scripture of yin-yang theory and all Chinese culture is rooted in Zhou Yi. Its core idea comes from the common law between nature and human. Essential attributes of Zhou Yi is that things moves in circles, never ends and are boundless and the driving force of this law is yin-yang while its essence is interaction between yin and yang. The five elements, yin-yang and Zhou Yi are basic framework of Chinese classic philosophy and cultural speculations. The five elements are basic knowledge about materials

composing everything and law of their development. Yin-yang reveals two contradictory aspects of a thing in its continuous movement. Based on The five elements and yin-yang, Zhou Yi develops from divination into a theory that systematically interprets and generalizes the world view.

The influence Taoism had on ancient urban planning in China mainly reflected in following aspects: Firstly, ideas of images abstracting from viewing promote formation of the idea about reconciliation with heaven and earth in urban spatial layout in ancient China and it always exists in ancient urban planning. Secondly, armomancy and other analogous ideas that Zhou Yi contains were applied to city planning and the basic feature that number is important for ancient urban layout was formed. Six and nine are often adopted in determining the number of many physical objects in architecture since they represent grandness, maturation, copiousness and consummation in the image-number system.

Fengshui

Urban morphology is a living environment system that contains deep cultural significance instead of a simple geometric patchwork. It is known that every nation is the creator of their living environment. Although the environment is related to external conditions, the more important is expression of their inner consciousness under corresponding cultural concept. As one of the three birthplaces of city, China has had well-developed urban civilization and culture from everlasting When analyzed from the perspective of historical development. And its most distinctive part is profound urban design and site selection of a city according to fengshui.

In construction of ancient cities in China, some artificial measures also were taken to cover the shortage of environment that is ominous according to fengshui. For instance, in planning and construction of Chang'an city in Tang Dynasty, the southeast terrain is higher than southwest terrain, which is thought detrimental in fengshui. Therefore, a pool was dug in southeast direction to lower the terrain, which became a pleasant scenic spot. Then a temple and two high wood towers were built to make the southwest terrain rise. In addition Guangzhou city in Ming Dynasty was also an example.

Conclusion

Material culture of a city is just like its skin, whose development cannot be separated from material culture elements, such as houses, streets, traffic and public buildings. System culture is like skeleton of a city and it provides the guaranty for urban material and spiritual culture. Meanwhile spiritual culture is soul of a city. These three types of culture have influenced and shaped urban morphology together. Most of ancient urban morphology in China was quadrate and axial symmetry was applied to the urban layout while its plane profile and structure appear as regular and square. This urban morphology represents an idea of crown and social rites. Under the requirement of pecking order and regalism, imperial palace is located in the center of a city in ancient China and covers a very large acreage. As for design of a city, ancient Chinese city also has a main feature: urban morphology, urban design, architectural design and garden design are highly combined together.

In conclusion, ancient Chinese city was made different for a long history and cultural characteristics it contains. Produced under a macro social background, it fully reveals the essence of traditional Chinese social life and the guiding ideology for urban construction contains quintessence of traditional Chinese culture.

Morphological evolution of urban form components in the Historical Peninsula of Istanbul

Ayşe Sema Kubat, Eren Kürkçüoğlu

Urban and Regional Planning Department, Istanbul Technical University.

E-mail: kubat@itu.edu.tr, ekurkcuglu@itu.edu.tr.

Abstract. *Communities transform urban spaces according to their socio-cultural structures, needs, principles and policies. This process occurs either as entirely rebuilding of the space, or as constructing the remaining with the trails left by previous societies. Thus, several cultures generate a physical and social mosaic within the same urban space over time. Certainly, the most apparent reflection of this mosaic can be observed on the morphological structure of the space. City blocks, transportation networks, open spaces, landmarks, monumental buildings and urban facilities come forward as the most prominent components through the transformation process of urban morphology. From this perspective, the Historical Peninsula of Istanbul can be defined as a unique mosaic: The reflection of the cultural features on the urban space can be seen by the variation of urban form components from Pre-Historic period to the present. The aim of this study is to evaluate how different cultures have transformed the morphology of the Historical Peninsula of Istanbul through history. Morphological structures and urban form components were analyzed through old maps in four periods: Greek, Roman, Ottoman and Republican. With the determinations obtained by mapping techniques, the transformation ratio in morphological structure has been examined comparatively via urban form components. In this context, the impact of cultures on urban morphology has also been discussed. According to the findings of the study, 16% of the components has been existed throughout all periods, 68% destroyed in the process, and the rest survived by being transformed or appeared in a certain period.*

Key Words: *Istanbul, historical peninsula, urban history, urban morphology, urban form components*

A brief history of Istanbul

Istanbul is one of the most dominant cities of the world throughout the history. Strategically situated at the edge of a volatile region of the world, and straddling the eastern and western cultures with a long, rich history. It became capital city for two dominant empires and it can be considered as the stage of those cultures that constructed it.

Istanbul is the only city in the world that sits astride two continents Europe and Asia and it was the capital of three great Empires throughout its history: Roman, Byzantine and Ottoman Empires. For 27 consecutive centuries, 3 civilizations; Greeks, The Romans and The Turks built many structures like palaces, stadiums, bathhouses, roads, etc. In each period, the city was destroyed, next generation simply rebuilt on the top of the ruins of the past, adding their own layer. So the city became an unique mosaic with the surviving remains of different periods and cultures.

The first traces of human habitation date back more than 300,000 years in the Yarımburgaz caverns. Between 685-680 BC, The Megarions, inhabitants of the city of Megara (Greece) found the city of Chalcedon, which is located around Kadıköy of today's Istanbul. The transformation process of Marmara Region's morphology extends back to 18 thousand years ago. Current form of the region was shaped 3000 years before present.

In this study, schematizations and geographical information systems are used for historical analysis. Old engravings and maps of historical peninsula are scanned and documented digitally. Then, layers of different eras are georeferenced and digitized for comparing the morphological

situation of different times. In the schematization process, Historical GIS is used to display, store, analyze and compare data and track changes of Historical Peninsula in time.

Greek Period (Byzantion)

In 7th century BC, a man named “Byzas” who was a member of a Dorian Greek sailor group from Aegean Sea constructed a Greek fisher village called “Byzantion”. According to the records, the origin of the village is based on 667 BC, so it can be supposed as a significant reflection of Greek Colonization Movement (750-550 BC). Byzantion was a typical colonial trade city “polis”, which refers to a classical construction of a city and centres on ideas of self-governance, autonomy and independence, with a significant focus on the public realm. The acropolis [place for worship] and the agora [marketplace] were the two major anchors and public spaces linked by wide paved streets in a highly ordered manner. Along with those two main parts of the city, Byzantion had many several urban form components which were devastated by following communities: (I) The nucleus of the city (The first of the seven hills, which Topkapı Palace and Hagia Sophia are located today, surrounded with city walls), (II) The Acropolis (Location of Topkapı Palace), (III) Agora (A grand bazaar), (IV) Amphitheatre, (V) Temples, (VI) Stadion (stadium / sport activities), (VII) Tetrastoon (theatre baths), (VIII) Baths and (IX) Residential Areas (Grid pattern) (Figure 1).

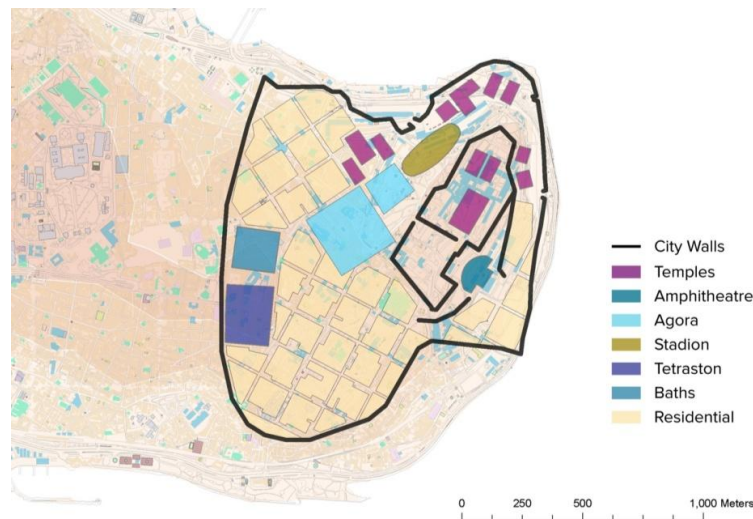

Figure 1. The City of Byzantion (667 BC – 196 AD) and urban form components.

Byzantion was the first nucleus of Istanbul, after this period, the city was developed along the western direction of Historical Peninsula. This continuity was mainly based on the topography of the site, followed by a development throughout the seven hills. The first hill which Byzantion was located is the most important region of Historical Peninsula, in terms of strategic location. It is the main intersection point of Marmara Sea, Bosphorus and Golden Horn. The hilltop was extremely convenient for Acropolis and appropriate to maintain control. However, the information for Greek colonial city Byzantion is very little, because only procedural diagrammatic maps and literature descriptions are available. Since any of the buildings could not reach today. The location of the city walls may be found in several maps.

Roman Period (Byzantium to Constantinople)

In 196 AD, Byzantium was incorporated in the Roman Empire by the Roman Emperor Septimius Severus and converted to Latin as “Byzantium” at 1st century. Byzantium had first been reconstructed in the time of Septimius Severus not just as a Roman city, but modeled on Rome itself, on and around seven hills. Later Constantine the Great chose it as his new capital (330 AD), renaming it “Nea Rome”, and it remained the capital of the eastern part of the Roman Empire. After the separation of Roman Empire into east and west sections, Eastern Rome declared the Nea Rome as a capitol city with a new name “Constantinople” in 395 AD.

In addition to Byzantium’s geographical and strategic location, forests and agricultural lands were the other effective reasons for becoming the new capital city of Roman Empire. Also, the existing city walls were providing security. After the Roman conquest in 330 AD, traditional city planning strategy employed by the Romans on any of their colonies, the Roman Castrum is determined both by the cardinal directions and the protective perimeter afforded by a wall. Public space was at the intersection of the two major roads through the town. Adapted to a hilly terrain and to existing building, this model can be applied to the growth and development of Istanbul during the classical period. The deliberate hierarchy of spaces and the protective quality are present on the larger scale. The old temples and structures were not ruined down, but the whole city was reconstructed by Constantinus I. Also he applied the planning idea of zoning with the inclusion of 14 separate administrative zones similar to Rome. However the road system was totally different; instead of the grid pattern of Rome, Constantinople’s pattern was quite organic. “Mese Street”, which starts in front of the Golden Gate through the historic core of the city, was the main ceremonial artery of the whole structure (Figure – 3).

In this period, urban form components can be listed as follows: (I) Acropolis (from Greek period), (II) City Walls (renewed), (III) Necropolis, (IV) Mese Street (the main artery), (V) Golden Gate (for ceremonies), (VI) Constantinus Forum, (VII) The Great Palace, (VIII) Hippodrome and Obelisks, (IX) Baths, (X) Aqueducts, (XI) Churches (Figure 2).

Figure 2. Constantinople (324-363 AD) main urban form components.

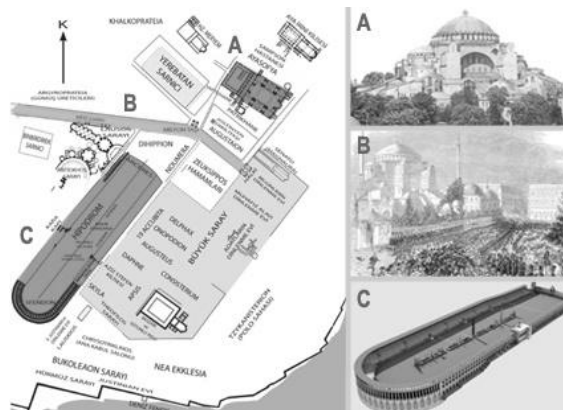

Figure 3. Hagias Sophia Church, Mese Street and Hippodrome.

Between 4th and 5th centuries, the Emperors gave importance to the city centres that reflects to Constantinople with constructing new forums. Forum Bovis and Forum Arcadii, which were the two important focal points of the forum chain, constructed along the main axis on Mese Street. In the 5th century, the city walls were renewed by Theodosius II. The city was enlarged with the construction of the new defensive wall nearly a mile and a half to the west of the Constantinian circuit. By those improvements and the growth of population; the land was extended from 6 km² to 14 km².

In this powerful period of Constantinople, new harbours and warehouses were constructed, public spaces within the old Severan walls were restored and renewed. Architecture and statuary have gained more importance in Roman period; in addition to the newly constructed buildings, streets, piazzas and forums were enriched with obelisks and monuments. Also, administrative and religious buildings were all decorated with ornaments and mosaics. This power and glory began to collapse along with the 7th century in consequence of plague, wars and upheavals, disasters (earthquakes and fires) and economic constraints.

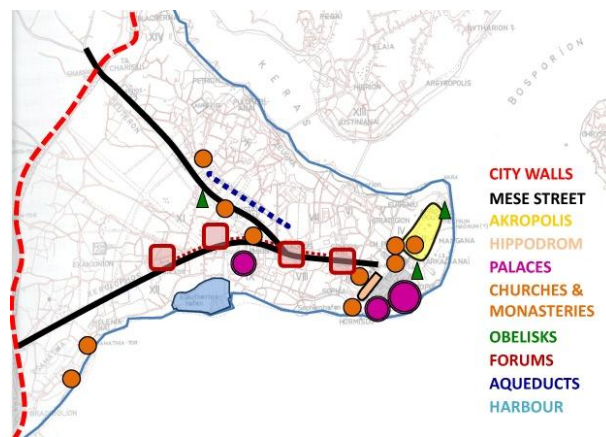

Figure 4. Constantinople (4th – 7th Centuries) main urban form components.

The collapse of the city started with the Arabian and Bulgarian attacks at the beginning of 7th century. A large part of the city was demolished and the identities of the monasteries, churches and public piazzas have changed. This devastation and transformation continued until the 10th century, on the other hand, the city became a religious centre. 25 churches were restored and 8 new churches were constructed. Before the 9th century, the harbour on the southern part of the city was ruined and economical activities were transferred to Mese Street and Haliç. At the beginning of the 12th century, Galata and Haliç districts were besieged and the Great Palace and Mese Street were destroyed.

Between 12th and 15th centuries, city walls, palaces and monasteries were reconstructed. It was clear that the city no longer had the power and glory of the previous centuries. The old city including Hagias Sophia Church, Hippodrome and the Great Palace was not majestic and strong anymore. Around the 14th century, Constantinople was no longer an empire, there were only small villages surrounded by city walls. Due to this decadence, the city was conquered by the Ottoman Empire in 1453. After the conquest, the first act was transforming the Hagias Sophia Church to a mosque, which shows the impact of culture and values to the city. This was also a symbol of a great transition between two major periods.

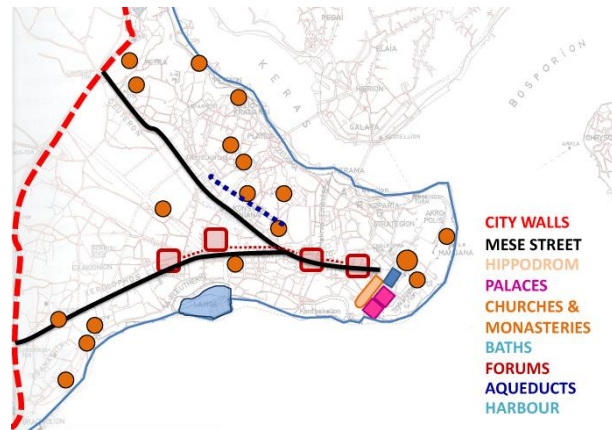

Figure 5. Constantinople (8th – 15th Centuries) main urban form components.

In order to summarize the Roman Period of Istanbul (Constantinople), the rise and fall of the emperors had shaped the structure and morphology of the city. At the end of Roman period, the city has grown to approximately 5 times of the Greek colonial centre and the growth control was achieved by the city walls in different time periods. Mese Street and the forum chain, which connects the historical core to the outer parts, were the most dominant urban form elements of this period. Churches were also significant elements to the fact that the importance of religion. Some components of the previous community have remained in this period; however the identity of many has changed. The topography of the site was the decisive factor for the development of the city. The hills were the main focus for urban form components, especially for constructing the symbolic buildings. In this way, the silhouette of the city has become more powerful and splendid.

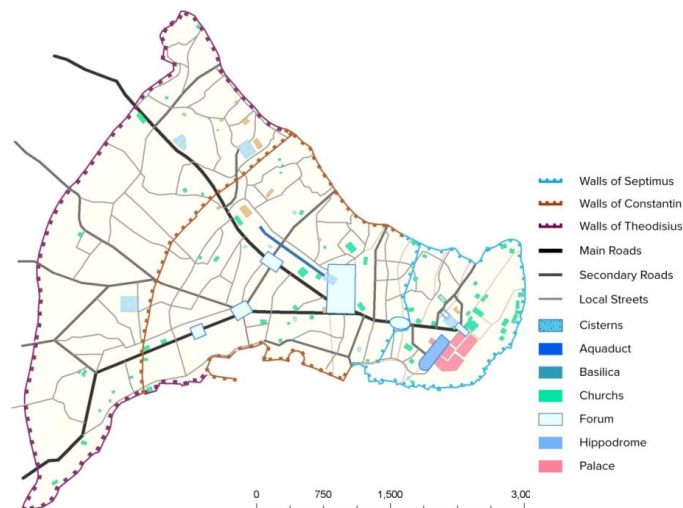

Figure 6. Constantinople, general morphological structure and urban form components of the Roman Era.

Ottoman Period (Konstantiniyye)

Following the conquest of Constantinople, Fatih Sultan Mehmed (Mehmed II) immediately set out to revitalize the city. He urged the return of those who had fled the city during the siege, and resettled Muslims, Jews, and Christians from other parts of Anatolia. The sultan invited people

from all over Europe to his capital, creating a cosmopolitan society that persisted through much of the Ottoman period. Fatih Sultan Mehmed was aimed to reconstruct the city, revive the economy and lay the foundations of a populous and powerful empire; so he repaired the city's damaged infrastructure, began to build the Grand Bazaar, and constructed Topkapı Palace (to the location of the Acropolis), the sultan's official residence. He was dedicated to the idea of renewing a devastated city as a capital of the world with a new structure.

Along with the revitalizing process, many constructions and reconstructions were performed such as renovation of city walls, construction of Yedikule Fortress, conversion of churches into mosques, generation of new gardens, formation of the nucleus of Grand Bazaar, decentralization of old harbours and warehouses to Golden Horn, reconstruction of markets and shops and construction of new market areas in new forms as “han” (inn / caravanserai) and “bedesten” (covered market place).

The Ottomans quickly transformed the city from a bastion of Christianity to a symbol of Islamic culture. Religious foundations were established to fund the construction of imperial mosques, often adjoined by schools, hospitals, and public baths. Also, other urban form components started to be formed by the effect of Islamic Culture. A new settlement unit “mahalla”, which developed around a small local centre including its own mosque, han, market area and bath, began to emerge all across the city⁵⁴. Furthermore, a new formation of the Islamic Culture “Complex (Külliye)” which contains a mosque, an institution, a madrasah (religious school), a library, a clinic (darüşşifa), kitchens, a bathhouse (hammam) and a fountain, was a permanent and unique component of this period (Figure 8). In addition, many churches from the previous period were converted into mosques. Mese Street was henceforth called as “Divan Yolu” and Hippodrome was converted into a piazza and renamed as “At Meydanı”. In summary, main prominent urban form components of Ottoman period can be listed as follows: (I) Mahallas, (II) Mosques, (III) Complexes (Külliye), (IV) Madrasah, (V) Palace (Sultan's residence), (VI) Han / Bedesten, (VII) Baths, (VIII) Market places, (IX) Harbours and Warehouses, (X) Aqueducts, (XI) Trade Centres and (XII) City Walls (Figure 7).

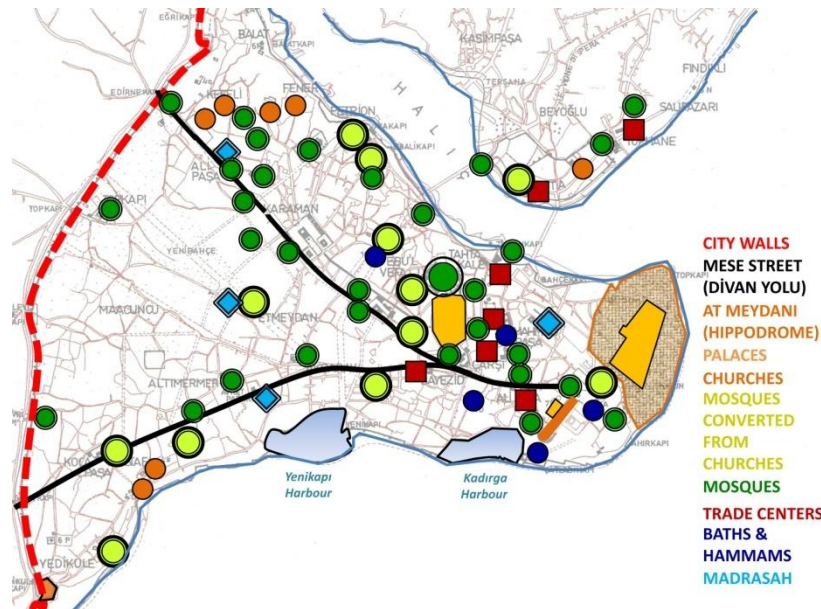

Figure 7. Konstantiniyye (15th – 16th Centuries) main urban form components.

⁵⁴ According to the records of the Ottoman period, there were 180 neighborhood units with the main characteristics of a “Mahalla”.

Figure 8. Süleymaniye Mosque and its complex (külliye).

Through the 16th century, commercial centres were at the same places as in the Byzantium Period. The most outstanding commercial areas were between Divan Yolu and southern shores of Golden Horn and Galata. As well as the eastern shore of Bosphorus began to develop in commercial activities, especially Üsküdar, the opposite side of Historical Peninsula. Also the residential areas were significantly developed; settlement extended from Ayasofya (Hagias Sophia) to Beyazıt, Şehzadebaşı and Fatih districts. Moreover, new settlements started to emerge on the shores of Tophane and Fatih, new villages erected in Ortaköy, Arnavutköy, Bebek and İstinye with a predominant Greek population. As in the previous periods, topography had an important role for development. The silhouette of the city was prominent for demonstrating the power and prestige. Therefore, the mosques were constructed on the peaks of the hills to be seen and perceived from various places. As a result; Bayezid Complex, Şehzade Complex and Süleymaniye Complex formed the unique silhouette of the Ottoman Empire.

In this century, Galata District (northern opposite shore of Historical Peninsula) had continued to progress; it was defined as “Pera” or “Istanbul Opposite” and contained three large districts: (I) Muslim district (around the Arap Mosque), (II) The district of the oldest inhabitants around the harbour and (III) Ortahisar Mahalla of the non-Muslim groups (on the slope). Different ethnic groups were lived in their own particular districts not only in Galata, but also all across the city with their own religious rituals and customs.

After this major structure of Ottoman Empire, the city had experienced various failures and changes between 17th and 19th centuries. The awakening of Western Countries in technology, science and economy had a negative effect on the Ottoman Empire, the population continued to increase. In the Tulip Period (in 18th century), the ruling class, court members and senior state bureaucrats started to leave the old quarters by the impact of French Palace and Landscape Design Movement. New palaces, villas, pavilions and mansions were built along the shores of Bosphorus and on the northern side of Golden Horn (Sadabad district). Those new buildings were constructed by the wealth of high bureaucracy and they were hidden from common people. So, the contrast and distinction between the “elites” and local people started to be more explicit. Also in the city centre, Western architectural and artistic styles (Baroque and Rococo) were dominant with the reflection of a new style in Nuruosmaniye Complex. Besides, new military and administrative buildings were constructed outside of the city borders as a nucleus of new districts; such as Selimiye Barracks in Üsküdar, Humbarahane Barracks in Halıcıoğlu, Arsenal Barracks in Tophane and Artillery Barracks in Taksim. The number of “han”s (the symbol of commercial activities) had nearly tripled at the end of 18th century. Lastly, 90 great fires devastated various parts of the city and almost all of the wooden houses were destroyed throughout the 18th century.

In the 19th century, Galata was the commercial centre of Istanbul which includes business centres, banks, shopping arcades and luxury shops. Meanwhile, Karaköy which situated on the shore just below Galata, had became a dynamic commercial centre. The old traditional shops and markets were still concentrated on the Istanbul side.

Until the middle of the 19th century, the image of Istanbul had been characterized with its mosques, tall minarets and their domes with a harmony. In this century, barracks, government buildings, banks and shopping arcades were more predominant on the overall city structure. Also, there were many new developments in transportation; as well as the construction of new roads, ferry boat voyages were increased and a new railroad system was constructed.

Republican Period (Istanbul – Modern Age)

The modern age of Istanbul had started with an administrative reform followed by the idea of making Istanbul as a “symbol of civilization” in 1839. During the truce period before 1923, there were two different pattern typologies in the opposite shores of the Golden Horn; flats and trade units in Galata-Pera district and crowded housing units, mosques and complexes in the Historical Peninsula. In the very first years of Republic, the administrative units moved to Ankara after becoming the capital city. The most important urban renewal project was applied in Beyazıt Square and also other applications were intended to create small green areas, recovering the streets and extending the tram line. Another important project was the Taksim Square Plan, which made by the Italian sculptor Canonica.

In the first half of 1930's; three urban planners A. Agache, H. Lambert and H. Elgoetz proposed many projects for the city's future. The most important proposals were the 2nd degree streets around the landmarks, industrial sites out of the city centre, enrichment of the existing railway system, green and shaded streets and increment of sea voyages instead of constructing a bridge on Bosphorus. Most of them were minor proposals to increase the quality of the urban structure; however the major changes affecting the morphology of the city first came with the Prost Plan in 1937.

Henri Prost aimed many objectives to find the solutions for the problems of the existing city structure: (I) Creating modern infrastructure and flexibilization of transportation system, (II) Conservation of the topography, urban pattern and architectural landmarks, (III) Restriction of the building heights, (IV) Improving the recreational needs, (V) Making the historical and cultural buildings prominent. In line with these objectives, new piazzas, boulevards, streets, stadiums, exhibition areas, opera houses and monuments were constructed (Figure – 9). The plan was revised after 1950 and some of his suggestions were implemented, while some of them were suspended.

There were some negative results of the plan: (I) Prost wanted to protect the historical pattern but the old neighbourhoods were not conserved, (II) During the construction of new roads, some important historical buildings were demolished, (III) With his suggestion of the industrial area in Haliç, the water was polluted and old settlements through the coastline were ruined, (IV) There plans of Üsküdar, Kadıköy, Galata and Beyoğlu were not integrated.

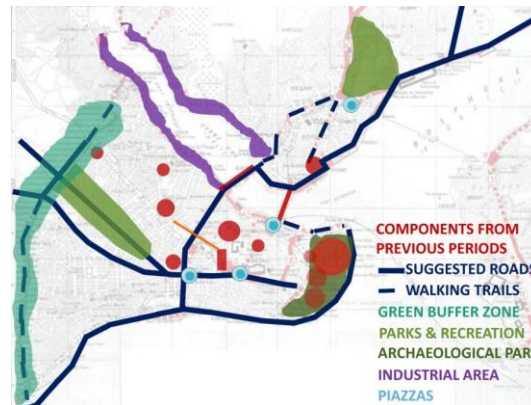

Figure 9. Henry Prost Plan (1937), proposals and new urban form components.

In Menderes Period (1950 – 1960), new major and primary roads were constructed in Historical Peninsula with the revision of Prost Plan: Vatan and Millet Streets, Ordu Street, Sirkeci - Florya Boulevard and Şehzadebaşı – Edirnekapı Roads. The north-south belt Atatürk Boulevard was extended, Barbaros Boulevard was constructed towards the northern direction of Beşiktaş. The hills over Haliç were transformed into squatter areas with the influence of the industry. New piazzas such as Aksaray Square, Eyüp Square and Eminönü Square were generated. During all these applications; lots of historical landmarks were destroyed or moved to other places, approximately 7000 structures were demolished or assigned to government, hotel buildings were constructed into the green zone near Taksim and a huge population migrated from Anatolia to Istanbul in this period. Informal constructions started to dominate and threaten the structure of the city and the boundaries were exceeded, in the meantime, the morphology of Historical Peninsula has been damaged and changed.

After 1970's, construction practices has increased. Two bridges (1973: Bosporus and 1988: Fatih Bridge) gave new directions to the development of the city. In the last 30-year period, Istanbul has become a megalopolis. Contemporary Istanbul is not just one of these historical phases, but a mix of them. The modern project of a new history-less Istanbul is being reevaluated as the city becomes increasingly diverse. The new city has a vibrancy resulting from a recent explosion in population growth and is searching for a new identity. While it does draw on a magnificent legacy from its past, it also faces new challenges as population and economic pressures force the city to adapt, evaluate itself and change.

Intertemporal transitions: from Byzantion to Istanbul

Byzantium to Istanbul (2700 years): Byzantium had very little covering area when compared to today's İstanbul. Only some of the walls and statues are remaining today in Topkapı Palace. The list of the temples and other civic buildings are described in literature, but nearly no maps or engravings can be found describing the city form.

Constantinople to Istanbul (1700 years): Constantinople had a main axis known as Mese Street. In fact, the word “Mese” means middle road, indicating centrality of this street. Mese was the center of economic and social activity, surrounded by colonnaded shopping centres.

Konstantiniyye to Istanbul (560 years): Like Constantine, Mehmet the Conqueror embarked on a building program when he appropriated Istanbul in 1453. As an example of religious tolerance, he retained Hagias Sophia and turned it into a Mosque. Mosques take over the civic services of the city, and the rest of the city fabric re-centres around these spaces and divides into a series of cellular neighbourhoods. The streets congest as the city encrusts itself. In the late Ottoman period, outside pressures lead the emperors to reconsider the role of the city as a model for development of the nation and empire. Looking back to the West for inspiration, late Ottoman emperors began to employ French city planners to re-envision Istanbul in Western image, re-inscribing thoroughfares and public spaces that had disappeared during much of the Ottoman rule. Taking the strategic advantage of fires, various neighbourhoods were redrawn with orthogonal lines, new public spaces were built and roads developed to deal with an increase in population and new transportation technologies.

The Historical Core: From the first settlement to contemporary Istanbul, the Seraglio (Sarayıburnu) was always a sacred place. In Greek and Byzantine periods, the hill in the northern part of the core was Acropolis. In southern side, just outside of the inner city walls, tremendous church of Hagias Sophia has been built. In same area, the Great Palace and Hippodrome has been built, where Blue Mosque and Sultanahmet Square stand today. After the Ottoman conquest, Acropolis was replaced by Topkapı Palace which is the main palace of all emperors. The hippodrome and Great Palace was mostly destroyed in early Ottoman period, thus Blue Mosque has built in the place of Great Palace. The ruins of hippodrome were conserved and became a square.

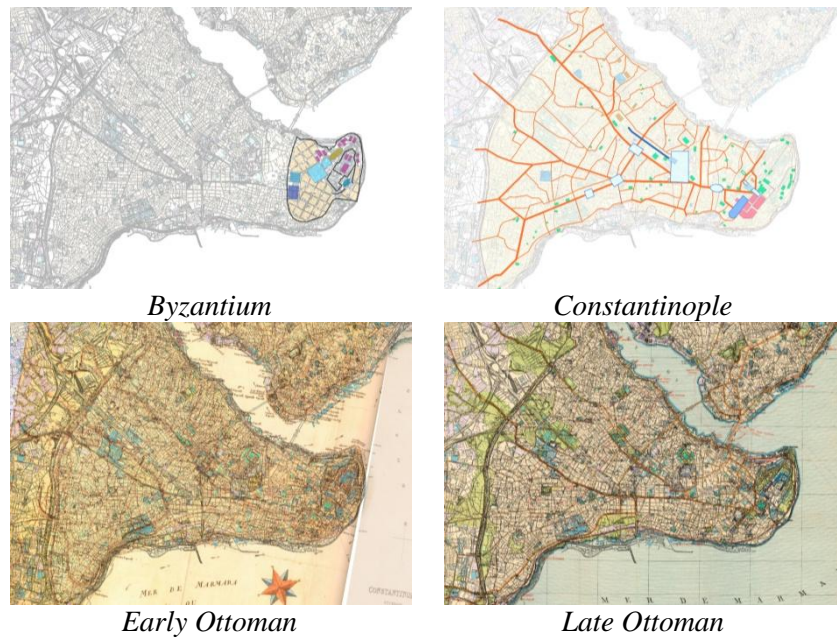

Figure 10. Istanbul, morphological transitions between historical periods.

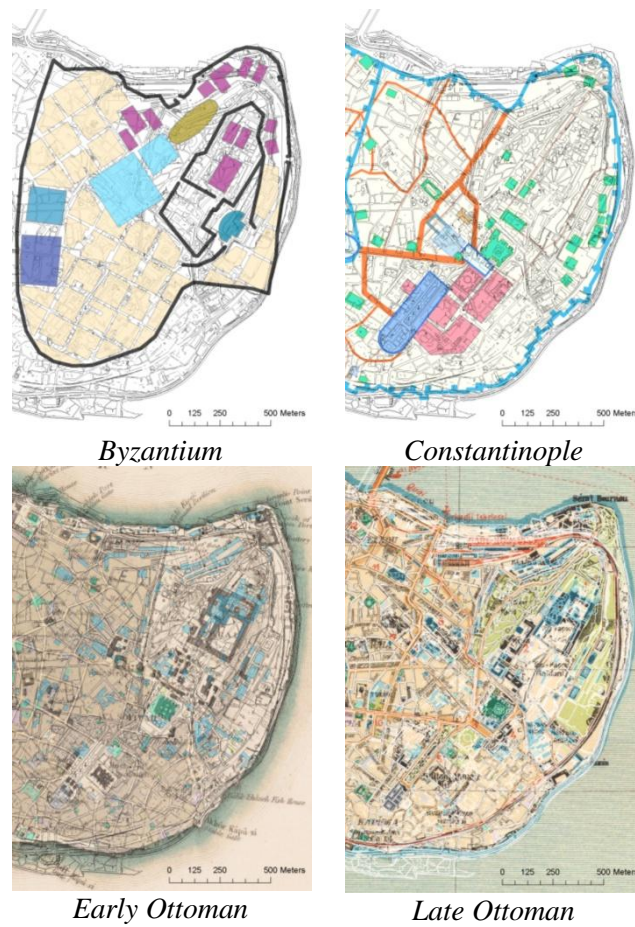

Figure 11. Morphological transformation of the Historical Core of the Peninsula.

Forum Constantin: The Forum of Constantine was built outside of the old walls. It was circular in shape and had two monumental gates to the east and west. The column of Constantine which still stands upright and is known as Çemberlitaş was erected in the centre of the square.

Saraçhane (Aqueducts): Aqueduct of Valens is planned and begun already in the time of Constantine the Great (died 337). It ended in a great reservoir in the vicinity of the Forum of Theodosius. Today, the area is in the quarter of Fatih, and spans the valley between the hills occupied today by the Istanbul University and the Fatih Mosque. The surviving section is 921 metres long, about 50 metres less than the original length. The Atatürk Boulevard passes under its arches.

Conclusion

Throughout all periods, the North-eastern point of the Historical Peninsula was always a sacred & special place since the first settlement. The main morphological characters of Roman Empire, main axis (Mese), Hippodrome, main Palace and Churches with more diagonal streets were made. Mese is still the main road approaching to the historical core area as “Divan Yolu” today. In Ottoman Era, there was lack of planned public open spaces. Since, the mosques were the main nodes of public spaces. The diagonal, straight streets and wide open spaces of Roman city were lost and more organic Islamic pattern appeared.

When the urban form components are examined in detail through different periods; it can be observed that the predominant components of each period are different. In Greek Period; the city walls, Acropolis, Agora and the temples were the main components. With the growth of the city and change of culture in Roman Period, the components which became dominant were new city walls, forums, Hippodrome, Mese Street, aqueducts, churches and monasteries. In Ottoman Period, the walls were nearly same but the most predominant elements were the mosques, which are the main urban form components of the Islamic Culture. In addition, public spaces were transformed into trade areas, Hippodrome was transformed into At Meydanı, Mese Street were renamed as Divan Yolu, new palaces, complexes, harbours and mahallas (neighbourhood units) were constructed. In modern period, a part of the prior components were demolished during new planning and application practices. New roads, open spaces, cultural and administrative buildings and defined function areas were constructed.

When comparatively considered, it can be seen that some of the components are common through all periods, which are city walls, palaces or administrative buildings, aqueducts, monuments, piazzas / public spaces, warehouses and religious buildings. (Table – 1) Almost all of them are still surviving today, although each community was settled on the ruins of the old ones. There were radical differences on the general morphology of the city, just like the Islamic structure of the Ottoman Period with its mosques, quiet and secluded lifestyle, narrow streets and cul-de-sacs in contrast with the Roman culture in such ways. However, urban form components are the remaining traces of the past, even if the general morphological structure of a city has transformed. As well as their importance in historical time sequence, these elements can also be informative landmarks for subsequent periods of time. In this context, Istanbul has a unique mosaic in terms of reflecting different periods. As an epilogue, Istanbul is a palimpsest of geographical and topological preconditions overlaid with multiple layers of history and urban culture and as a contemporary metropolis.

A code for the Islamic cities of the Gulf

Attilio Petruccioli

Department of Architecture and Urban Planning, Qatar University, Doha.

Abstract. *The paper demonstrates that the urban fabric of the traditional cities of the Islamic countries, beyond an apparently chaotic image, possess a logical structure, that contains all the information needed for the formulation of a contemporary urban planning code.*

Key Words: *History, fast growing Islamic cities, typology, urban fabric.*

Introduction

The subject of this paper is the traditional Islamic city, or, those settlements of the southern world inhabited and politically controlled by peoples of Islamic faith, as they appeared at the height of the colonial movement of the nineteenth century. The fundamental question is whether these prevalently spontaneous urban constructions are the result of anarchic urban planning, or whether they possessed a complex code. I will demonstrate that the traditional cities of Islamic countries, beyond an apparently disordered image, possess a logical structure that contains all the information needed for the formulation of an urban planning code.

Islamic City

The traditional Islamic city is characterized by homogeneous and compact urban fabrics with building that is for the most part mono-typological, often enclosed in the circuit of their own walls. The chaotic appearance of the traces and building fabrics seen through progressive mechanisms of closure toward the outside and the labyrinthine course of the streets have stirred up the perplexity of Western travellers and the first scholars who confronted the cities of the Ottoman Empire and the Maghreb⁵⁵.

Beyond an initial superficial, subjective impression that all traditional Islamic cities have the same form—in reality they share the use and perception to which the foreign visitor is obligated—they differ from one another in the morphological conditions of their territory, in their origins and their cultural affiliations.

Dar al Islam has welcomed many ethnicities and cultures, which before the Hegira had developed over the course of many centuries their own idea of space and a different relationship with the landscape. The Arab world tied to the deserts and the steppes of arid lands like the

⁵⁵ It is worth summarizing the various Orientalist positions on the Islamic city. The merit of extending the discourse from the monuments to the urban fabric goes to the brothers Georges Marçais and William Marçais who emphasized the essentially urban role of religion. See Georges Marçais, "L'urbanisme musulman," in *Melanges d'histoire et d'archéologie de l'occident musulman, 1: Articles et Conférences de Georges Marçais* (Algiers, 1957), pp. 219-231. Also see William Marçais, "L'islamisme et la vie urbaine," in *Comptes rendus de l'Académie des Inscriptions et Belles Lettres*, (1928), pp. 86-100; G. von Grunebaum and R. Brunschvig share Marçais's spatial model as well as a certain resistance to the "irrationality" of the Arab urban fabric. Only after the sixties, with the conference at Oxford, did these Orientalist propositions begin to be challenged. In this conference, Albert Hourani noted the African origin of the Marçais model, and every other participant underlined the impossibility of generalizing from a single model since the Islamic city is a complex phenomenon, extended in both geography and in time (see Albert Hourani and S. M. Stern, eds., *The Islamic City: A Colloquium* (Oxford, 1970).

Arabian peninsula, in the dialectic between nomad and sedentary, barricaded in oases, has developed a conception of double space: a love of closed and delimited space, from the short perspective, and at the same time an idea of a serial and repetitive architecture of simple elements. The Turkish world is formed in the steppes of Central Asia where the main animal of transport is the horse, which can range infinitely like the eye of the rider. Its space is therefore open, intolerant of limits and enclosures. Beginning in the tenth century, this conception will have to compete first with the Persian world and then with the classical world of Byzantium, ending up profoundly influenced by them. Then there is the Berber world, installed in the Atlas Mountains, that has marked, with its small tribal settlements with no hierarchical nodes, many cities of the Maghreb.

The fundamental fact is that the traditional city with the coherent development of its building fabric, a balanced relationship between residential and monumental building, and a cautious and proportioned use of technology is good, while the contemporary city, built by the great-grandchildren, has no character, like the neighbourhoods of Riyadh or, with an excess of character, is always inappropriate, as at Dubai.

Let's disregard Dubai, which, in its shrewd synthesis of real estate investments and astonishing effects (Miami + Las Vegas), presents itself unfortunately as a successful model to the mayors of the Arab world and beyond, and is in any case an exception. Rather, Riyadh in its ordinariness is an emblematic example⁵⁶.

The failure of the imported Western codes

Beginning in the 1950s under the influence of ARAMCO, the Arabian-American Oil Company, the cities of Saudi Arabia developed according to master plans based on a geometric grid of streets and minimum residential lots. In 1953 in the case of the Al Malaz quarter, called New Riyadh, for government employees, the physical pattern follows the grid with the hierarchy of streets, regular rectangular blocks and square residential lots with 400 square metres of surface. With regard to the traditional city, two new concepts are introduced: very low density, about a fifth of that of the old city, and a large area devoted to streets that end up covering half the total.

The introduction of the principle of detached setbacks has almost automatically imposed the building type of the one- or two-storey villa. In 1968 the plan of the capital was entrusted to Doxiadis Associates who, next to the zoning for the new city, confirmed the choice of the geometric grid, proposing a super grid divided into twelve smaller grids measuring 2 X 2 km. The standard lot is 400 square metres, or 20 X 20, but in low-income neighbourhoods the standard is reduced to 150 square metres. In spite of this, the gross density is very low, with sixteen units per hectare, or 87 inhabitants per hectare⁵⁷.

In the city of Riyadh, the minimum lot sizes with different standards for different areas, related to the London Building Act of 1844, have institutionalized social segregation by income, contrary to the custom of the traditional city, in which different social classes lived side by side. The confirmation of the setbacks, which is inspired by the London Building Act of 1894, and the concession to buildings with separations of only two metres of window openings with a view onto the land of one's neighbour, has in fact obscured the concept of privacy. In Riyadh, neighbours are compelled to arm themselves with panels of corrugated plastic, to extend the height of fence walls to cover the view⁵⁸.

⁵⁶ On Dubai see: Deeba Haider. "The Growing Pains of Dubai: a City in Search of its Identity", in *The City in the Muslim World*, edited by S.K. Jayyusi, R. Holod, A. Petruccioli and A. Raymond, vol. 2, pp.1063-1084, Brill, Leiden, 2008.

Figure 1. Detached cottages in the city of Riyadh.

A paradoxical situation has been created, a dichotomy between a code of behaviour and long-established customs based on the Koranic Code opposed to the urban planning codes of the municipalities, derived from Western culture.

Riyadh is a city of the modern era, a product of a universal crisis in urban planning of the 20th century that has seen the organic city of the past slowly break up into separate mono-functional parts and architecture become the expression of individual languages, based on self-referential principles. In the 1970s the detachment from history was complete, and rules became increasingly more abstract. Today there is the imperative to re-establish the codes for the contemporary Islamic city, not by means of a universal manual or a pragmatic *laissez-faire*, but rather through the understanding of the processes that in every specific region of the Dar al Islam have given physical form to the necessities of society. This is not a case of codes that are a collection of forms frozen in time like the “Recueil...” of J. N. L. Durand, but rather a patrimony of stratified information jealously guarded by history in the urban fabric of the traditional city.

The Shariah is not an Urban Code

In the context of Islamic legal tradition, this concept of continuity within a tradition that changes is present. The first schools of Kufa and Medina, respectively Hanafi and Maliki in the first century of the Hegira, try to mix the different local traditions with the Koran, to make the ideal doctrine come together in the *sunnah*⁵⁹. With the taking of power by the Abbasid Dynasty, a return to the purity of the law is imposed—so that it might reform the *sunnah* of the Umayyad, giving authority to the most ancient sources—and in the last analysis to the Prophet through the numerous *hadith*⁶⁰. The potential contradiction between *sunnah* and the new *hadith* was rewritten by the Shafia school following the universalist principle, according to which a norm must be recognized not only locally, but by the entire *ummah* of believers. The norms relative to the city contained in the whole of the Koranic Law, basically unchanged after the ninth

⁵⁹ On Islamic law, see: N.J. Coulson. *A History of Islamic Law*, Edinburgh, Edinburgh University Press, 1964; Schacht, J. *An Introduction to Islamic law*, London, Oxford University Press, 1964. The Shafia school recognizes the *sunnah* as the second legal source after the Koran. For Al-Shafi, *sunnah* is the exemplary behaviour of Mohammed inspired by God, while for the early schools it was the local tradition where these were located.

⁶⁰ Besim S. Hakim. “Mediterranean urban and building codes: origins, content, impact and lessons,” in *Urban Design International*, 2008, 13, p. 5.

century, are measures that tend to prevent changes that might disturb the moral integrity of the community or destabilize the peace of the neighbourhood. These are proscriptive meta-principles rather than prescriptive rules⁶¹. They have more of a social value than a physical one; they are rules of conduct rather than urban planning codes.

The Islamic Common Law is not an Urban Code

Among the treatises generated by the Shariah the most ancient are those of Ibn al-Hakam of Cairo (767-829 CE) and Ibn Dinar of Cordoba (827 CE), both lost, but cited by more recent authors. The treatise of Ibn al-Imam of Tutela (940-996 CE) contains numerous legal questions relative to the city and to building with specific cases about Medina, Cairo, Cordoba and Kairawan. After confirming the need for rights of interdependence between citizens and stating that the public can not be damaged by activities that occur in private, Ibn al-Imam discusses problems of the location of mosques and baths and harmful and polluting activities; he gives a rough definition of the hierarchies of the streets; he disciplines the use of the waters; he treats in detail the protection of privacy and the prohibition of outside views. An important role is played in the treatise by the discipline of contact between nearby walls—a principle reinforced by the Prophet in the period of Medina, whose *hadith* states that “a neighbour cannot prohibit another neighbour from inserting a wooden beam in his wall.”⁶². On the private level, the treatise protects the right of use of the property with the possibility of increasing the space up to contact with the adjoining property. It codifies the right to pre-emption of an adjacent property, a principle at the base of the social continuity of the traditional quarters. These are certainly principles that have an undeniable influence on the organization of architecture and urban planning—suffice it to consider that the problem of introspection conditions the opening of doors and windows and the height of buildings—but we are still in any case within the Common Law⁶³.

The concept of *fina*, on the other hand, is original and of great potential, an area of virtual relevance about a metre wide, along the outside wall of the building⁶⁴. It is not an absolute right since its exercise clashes dialectically with the public right, which establishes the control of the streets, the aqueducts, the emptying of the sewers, and garbage collection, ensuring that the public way is kept free and safe. *Fina* is a sophisticated and flexible concept that allows a limited “invasion of the field” without obstruction of the passage, through the use of protections from rain like gargoyles, downspouts, enclosed balconies or *musharabiyyas* or an occupation of the land like temporary merchant stalls outside the stores, seats or steps in front of the door of the house.

The impression one has is that the evolution of the Islamic Mediterranean cities rests on a shrewd interpretation of the *fina*, so that protective roofs can become porticoes and closed, and successively be transformed into an extension of the house, or, the stores can gain surface area

⁶¹ Besim S. Hakim, op.cit., p. 2.

⁶² Saleh Al-Hathloul, op.cit., pp. 97-102.

⁶³ With regard to the house, the treatises of the early centuries have left a series of restrictions that have undoubtedly had an effect on the character of the house: 1. The house cannot have stairs or a *mastaba* on the street, a rule not applied to semi-private streets of the quarter; 2. The doors of houses that face one another should not be placed on the same axis; 3. The lower windows must be located at a height that does not permit views from the outside; 4. The overhangs of the upper floors, whether *mushrabiya* cantilevered spaces must be high enough to allow for the passage of a camel with its load; 5. *Sabat* are not allowed on the public street.

⁶⁴ On the concept and practice of the *fina*, see: Ibn al-Imam, ms. in Algeri Al-Maktabah al-Wataniyah, n.1292, French translation: Barbier “Des droits et obligations entre propriétaires d’heritage voisins,” in *Revue algerienne et tunisienne de legislation et jurisprudence*, part 1, 1900 e part 2, 1901, respectively 1,141 e 143; see also Ibn al-Rami, *Kitab al-I’lan bi-Ahkam al Bunyan*, ms. in Rabat, Dar al-khizanah al-Ammah, n. A8 2834, respectively pp. 43-45.

in a moment of inattention of the *muhtasib*, the official in charge of the control of the bazaar⁶⁵. A particular case of the application of the concept of the *fina* is the *sabat*. This uses the air space of the *fina* on both sides of a street, giving a neighbour the possibility of building a "bridge" over the street, attaching itself to the property of the neighbour across the street. The result goes from a room resting on a row of joists or an arched vault, or held up by two posts on the ground; where the *sabat* is extended in depth there are real tunnels, which are the more propitious the more one moves away from the Mediterranean toward the Sahara Desert. If the *fina* explains in part the generative principles of the Islamic city, especially the building scale, it does not contribute to making the corpus of the Shariah an architectural and planning code. If we accept the idea that the structure of the organism is encoded like a descriptive program, an architectural and planning code of the Islamic city can be reconstructed only *a posteriori* beginning with the legacy of history.

It is an operation of reconstruction that must be carried out backwards, singling out typical behaviours, called reconstruction of the typological process of the house, of the building fabric and urban plan⁶⁶ (12).

Towards the New Urban Code for the Contemporary Islamic City

The construction of a code is therefore a task that can not ignore the local context. Among the many information that the typological process of the cities produces some have universal value like curves around the corners of buildings or the city walls; like the convergence of the paths on the city gates, which give the typical mark of leg chicken: like the layout of building fabrics in relation to the hierarchy of paths. Others will have a purely local character, primarily the choice of residential type so intimately tied to the family social unit, its customs and traditions. The residential type, has been said many times, does not travel, like the dialects it is rooted in the territory, unlike the cultivated language, expression of an elite often multi-religious and multicultural. The construction of a code means pick up the threads of continuity with history with attention to the genius loci, to the deepest traditions of society, which are almost part of its instinct. A basic theme is that of the courtyard house fabric. They are based on an archetypal idea of space: the fence, and widespread in cultures far apart as China, India and the Mediterranean sea. With the passage of time they gave way to extrovert forms of living (not only in Islamic countries, but in all countries at the time under the Roman Empire) based on forms of building types referred to the row-house and then to the apartment-house. In the compact suburbs of Western and Islamic countries the later building type has become the reference type. It should be stressed as row-houses and apartment-houses are not inventions impromptu but the steps of the typological process of the courtyard house, unlike the type of cottage house that reigns in American suburbs, which is a step backward from the "social" and the aggregate capacity of the courtyard house. I demonstrated how easily the adoption of colonial codes has dissected the city of Islamic countries, promoting alien building types and urban fabrics and contrasted with local traditions, social customs and religious rules. The case of Riyadh is the most striking.

⁶⁵ The occupation of public land must have been a usual practice in the traditional Islamic city, if an abundant literature relates the ordinances of the governors to repress it, often unsuccessfully: with regard to Cairo alone, we can cite the *risala* (treatise) of Ibn al-Shihna entitled *Tahsil al-tariq ila tahsil al-tariq*, which boasts of the measures taken by the emir Yashbak min Mahdi in the 15th century to rearrange the streets of Cairo. The *muhtasib* is the traditional inspector of the market. See: R. Levy. "Muhtasib," in *Encyclopaedia of Islam*, 1st ed., vol. 3, pp. 702-703.

⁶⁶ See A. Petruccioli, *After Amnesia*⁶⁶. *Learning from Islamic Mediterranean Urban fabric*, Bari, ICAR, 2007.

Figure 2. The proposed masterplan of one quadrant in the new expansion of the city of Riyadh.

The central theme of research, I am conducting in the Polytechnic of Bari, is centred on the courtyard house fabric and its application even in the new expansion of the Muslim city, in different climatic and cultural contexts. Taking in consideration all modern problems of traffic, parking and prevalence of the use of private cars, all different schemes have demonstrated their viability in terms of real sustainability, quality of social life offered by public spaces, semi-public and private in terms of performance compared to extreme arid climates. Versus a hypothetical expansion of the city by means of disconnected objects like slabs and towers as in Mostar, Essaouira, Fez and Antakia or by means of repeated endlessly cottage houses as in the suburbs of the Arabian Peninsula we propose to use fabric of courtyard houses. This is a real change of direction at 180 degrees, which opposes the traditional way of composing based on addition to a method based on subtraction: subtraction of paths, creation of voids for the collective life as sahn, courtyards of the mosque or caravanserai, subtraction of Courts for the private life. In the case of Riyadh it has decided to design a new quadrant of the city, an entire compound of 4 square km divided into sub-units of housing 500 x 150 meters, as prepared in the General Master Plan by the municipality.

Figure 3. A proposed neighbourhood in the quadrant.

Figure 4. The proposed urban fabric based on innovative design of a traditional layout.

The proposed scheme provides total separation between driveways giving access to each house, walkways, located at an altitude above and adopting a system based on a tissue of courtyard houses. All buildings are largely inspired by traditional types as you can still see in the old city of Al Darriyya. The project results in terms of building performance, high density with 65% of the area covered with three-story buildings and quality of public spaces, despite being a work in progress, shows that path taken is the right one.

Conclusion

In conclusion, the urban codes inspired by the western codes, adopted in modern times by the municipalities of Islamic countries have failed. They have designed expansion quarters very similar to the peripheries of American cities, and they have generated building fabrics and houses that are in clear contrast to the customs, beliefs and sensibilities of Muslims.

At the same time it is important to reaffirm that the moral precepts of the Shariah are not an urban planning code, even if they have indirect influence on building fabrics and types.

A planning code of the traditional Islamic city of the Mediterranean can be inferred only *a posteriori* through a capillary work of interpretation of the typical behaviours of the house, the building fabric and the urban plan of the traditional city. In the first place, it is possible to create a model that draws references from the *khitta* for the urban organism, the centrality and hierarchy of services, and the distribution of the individual quarters and from the typological variants of the behaviour of the urban fabrics an articulation of the fabric and the hierarchy of routes, and the aggregation of building types. It remains understood that planning standards like road sections, detachments, and quantity of services cannot be fixed at a universal level, but only at the local level, since they are the product of climate, materials and local building traditions, that is, diverse architectural cultures that Islam, on the basis of Sura 7 of the Koran, has always respected. I am convinced that the contemporary Islamic city has everything to gain if, instead of articulating in a vacuum architectural objects of abstruse form, separated by left-over spaces without definition, it filled that space with a continuous fabric of introverted architecture like the city of the past. That is, the practice of the Lego toys that work through mechanical addition and juxtaposition, would be substituted by the practice of the organic project of continuous fabrics.

From ‘a miserable town of 150 mud houses’ to ‘the city that never sleeps’: the transformation of Limassol’s urban form over the past 200 years

Ilaria Geddes

Department of Architecture, University of Cyprus

E-mail: ilaria.geddes@gmail.com

Abstract. *This paper describes PhD research, which uses spatial analysis to trace the development of the urban form of Limassol between 1883 and the present day. The research is specifically concerned with the street network and how this relates to different social variables such as ethnicity, educational level, and occupational status. It focuses on how these factors have changed spatially and over time, on analysing such changes diachronically using historical and contemporary maps (from 1883, 1933, 1960, 1987, 2003 and 2011), historical records and census data. This paper presents the findings of the first phase of the research, which analyses the urban morphology using space syntax methodology and block size analysis. Firstly, the space syntax model of the contemporary city is used to construct models of the city in the past based on historical maps, the changes in the accessibility patterns of the city are assessed across time. Secondly, the models are used to construct street block maps and changes in the block size of different areas are evaluated. The analysis shows that as Limassol grew, fringe belts developed around its historical core, partly along radial routes - former rural paths leading to surrounding villages - and then through the development of ring roads. Although the accessibility core of Limassol has shifted over time towards the inner ring road and further out into the contemporary city, the historical core still retains functions and properties typical of its former spatial characteristics. The results suggest that diachronic analysis and combining different approaches provides valuable evidence and facilitates an understanding of the ways in which historical formations of urban configuration influence the present life and form of the city.*

Key Words: *Space syntax, block size, fringe belts, diachronic analysis, Limassol*

Introduction

Diachronic analysis has substantially gained momentum over the past decade thanks to the spread of GIS technologies and software for spatial modelling, which not only allow the geo-referencing and layering of historical information related to the urban form, but also provide greater capabilities to store and analyse larger amounts of data as well as constructing more detailed analyses and accurate results. Interest in the historical processes which see growth and change of the urban environment has also increased as the importance of understanding the process of development in order to gain insight into the contemporary urban form has been recognised – it has even been suggested that the main aim of morphological analysis of the contemporary urban fabric should focus on understanding the transformations that led to the development of features peculiar to the contemporary age (Levy, 1999).

The ability to identify different morphological periods and urban typologies afforded by diachronic analysis provides the tools to develop an interpretive narrative as to what caused changes and to assess how the contemporary urban fabric is a reflection of past and present social, economic and cultural factors. The relationship between socio-economic and cultural conditions and the urban fabric is key to understanding the urban fabric to the extent that it may not be possible to ‘read’ form correctly unless we fully understand the cultural conditions which generated it and which are reflected in the ways additions to the an original historical core are mixed with or distinguished from the older fabric (Kostof, 1999). The issue of how the physical, material form of the city relates to social processes is inextricably linked to the dual nature of

cities as both physical and social entities – as the collection of material elements which make up the city and as a system of human activity and interaction. This is what Hillier and Vaughan (2007) term the physical and the social city, arguing ultimately that the city is one entity as “the physical and social cities act conjointly to produce significant outcomes”.

The relevance of diachronic research is that it does not exclusively aim at achieving an understanding of generative rules of urban development but it also provides methodologies for analysis comprising different analytical tools which can be used individually for assessment of past and contemporary urban forms as well as proposed developments. It thus also aims to inform contemporary design in its attempt to incorporate inherited street patterns and the built heritage within the urban landscape, enhancing its potential to enable a collective experience of urban space, thus fostering a collective identity (McQuillan, 1990).

This paper presents the findings of the first phase of PhD research focusing on how the relationship between physical elements of the city and social factors has changed spatially and over time. The analyses and findings presented here relate exclusively to physical factors - though they are framed within the socio-cultural context – and focus on how the urban form of the city of Limassol, Cyprus, has changed between the end of the 19th century and the present time. Space syntax methodology and block size analysis are used to describe the characteristics of the city at different points in time, assessing its spatial properties and the way its urban form functions. Spatial models of the city are constructed and analysed based on historical maps (from 1883, 1933, 1960, 1987, 2003 and 2011); elements added and changed between two periods are analysed quantitatively and qualitatively, while the formation of suburban areas, fringe belts, the development of a conurbation and changes in the centrality of city are assessed.

Limassol's urban development

Limassol has changed dramatically over the past 200 years; it has developed from being little more than a village described as a “miserable town of 150 mud houses of which 100 are Greek and 50 Turks” (Turner, 1820) to a sizeable city of over 180,000 inhabitants, which has “several reputations, ‘the city that never sleeps’ is one... thanks to the tourist area’s exuberant night life” (Marić, 2009). Limassol occupies the southernmost point of the island and is the largest port in the country, home of the 3rd largest merchant navy in Europe and a highly diverse city - as of 2011 3.6% of Limassol’s population were Romanian; 3.3% British; 3.1% Greek; 2.3% Russian and 2.3% Bulgarian, to name just the top five minorities. The city stretches east-west along the coast and expands to the hills at the foot of the mountain range to its north – although like other Cypriot cities density is low and sprawl is evident, it is somewhat more ‘compact’ than other cities on the island as its development is constrained by U.K. sovereign territory to its west and the mountains to its north. Much of Limassol’s development in recent years has thus occurred on the hills to the north and along the coastline to the east, the latter geared towards to the tourist industry.

The small town described by travellers during the first half of the 19th century was accurately represented in an admiralty chart of 1849, shown in figure 1. Although it is unclear whether the map covers the whole of the built area, specific elements of city, such as the fort, mosques, churches, the jetty and the water tower are marked, while the basic urban form of the historical town centre is recognisable in the area around the fort and the street of Agiou Andreou, parallel to the shoreline and becoming the street of Agkyras from the fort heading out north-west over the river – this was known to be the main commercial street during the Ottoman period (Severis, 2006).

Figure 1. Admiralty chart of Limassol, 1849, drawn by Lieut. Lord John T. Browne (survey by Capt T. Graves. Admiralty Chart 2074. 3.5 sea miles to one inch, London, National Archives).

Towards the end of the Ottoman period, Limassol develops as a city of proto-industrialisation, as the economy benefited from the stationing of British troops in the district, with consequent development of establishments and retail facilities in the town, partly meeting increased and changed demands due to social and historical changes (Katsiaounis, 1996). However, during this time geographical divisions related to ethnicity had become more and more spatially defined along with other social factors, such as social class – the town was divided into a Turkish and a Greek sector (west and east of the river respectively), a poorer area was expanding around the fort and the port, while the wealthier classes had established themselves further north around the church of Katholiki. Figure 2 shows the city in 1883 – it had clearly developed significantly towards the north and the east and it now included the street of Anexartisias, the main contemporary commercial street in the historical centre, while the large block of the Commissioner's deposit to the north is evident (later to become the hospital and police headquarters). The Commissioner's house, currently the home of the historical archives, is now also present in the top right corner of the map - the public gardens were later developed around this.

Figure 2. Map of Limassol, 1883, from Rodney (2001).

Heading into the 20th century ethnic diversity and spatial divisions are evident from travellers' records; by the 1930s Agiou Andreou is identified as the street with the highest

number of shops, with the Turkish bazaar is at its western end (towards Agkyras), meanwhile the British community had settled in the eastern end of the town around the public gardens while the Turkish continued to occupy the area west of the river and the Greeks the central area of the town (Peto, 1927).

The years of British rule see the development of much urban infrastructure along with the paving of former footpaths connecting the city to the surrounding villages and now forming the main radial routes 'sprouting' from the edge of the historical town centre out to the suburbs in various directions. Right after World War II, the first ring road of the city (Makariou) is built, starting just to the north of the Commissioner's house along a former ditch lined with a footpath and continuing further west to surround the whole city – this road is marked 'By-pass' in a tourist map of 1947 (figure 3) and it has now become a popular commercial and service street, while still functioning as a major vehicular route through the modern city centre.

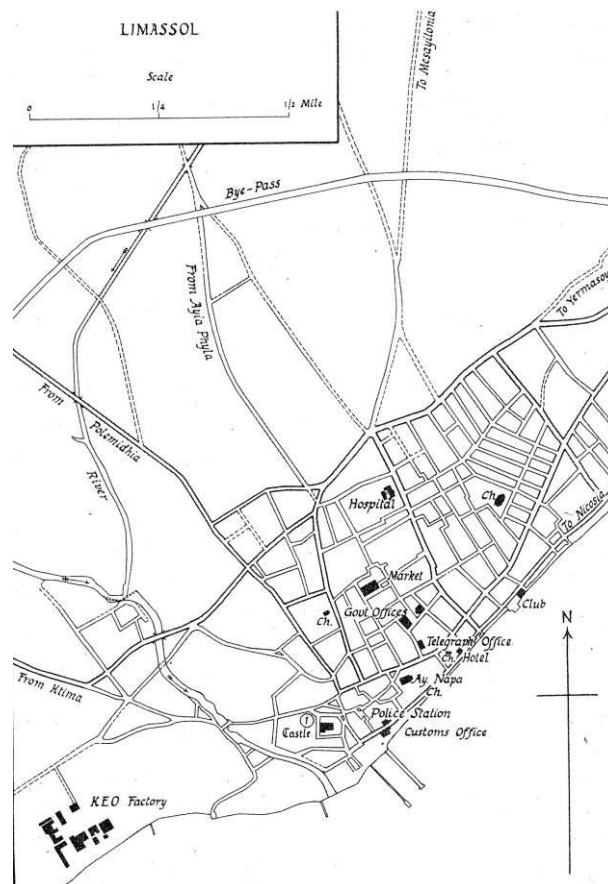

Figure 3. Tourist map of Limassol during the colonial period (Mangoian & Mangoian, 1947).

By 1960 the area between the edge of the historical core and the ring road is the focus of densification, while further development takes place to the north of Makariou; the densification is represented (though not fully) in a tourist map of 1974 (figure 4) where it is also clear that some land uses, such as the hospital, have shifted. The hospital has been moved to the former Commissioner's Depot - no longer in use since Cypriot independence in 1960 - while the building along the street of Anexartisias was reused to become the district office.

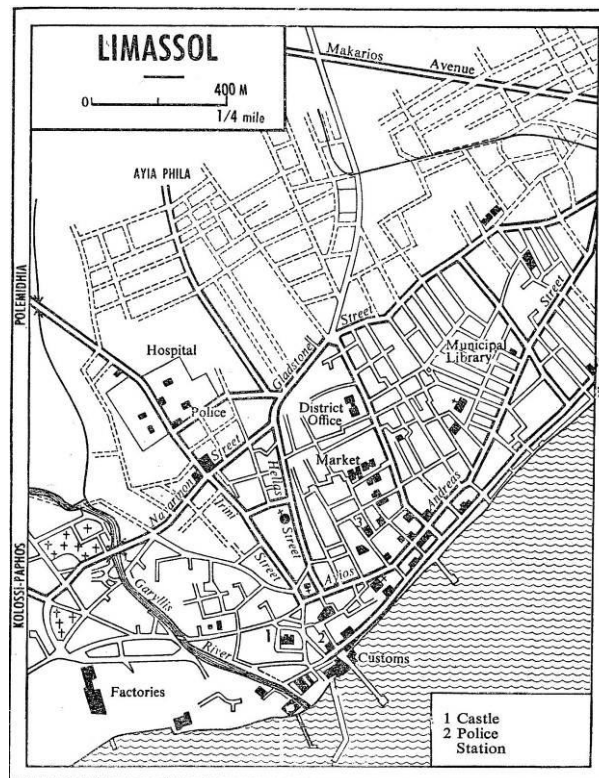

Figure 4. Tourist map of Limassol during the post-colonial period (Milliex, 1974).

Limassol grew after rapidly the 1974 Turkish invasion of Cyprus, when almost half of the island's population became refugees in need of housing. Consequently, a large number of housing estates were built at the edges of cities where land values were relatively low and large development areas available. Due to this and further expansion at a time when planning regulation was almost non-existent led to a rather fragmented urban fabric. Previous analyses of Limassol's growth have pointed out that uncontrolled urban development led to an uneven expansion of the city, creating a fragmented structure and leaving many gaps in the urban fabric (Kritioti, 1988). The motorway surrounding the city was built in the 1980s as far north as it was viable, 'demarcating' the division between the city and the villages to its north. The construction of the motorway also demarcated a large, low density fringe belt between Makariou and the motorway itself, but as the city grew further and densification took place, a second ring road was built in the 1990s connecting existing stretches of road and 'splitting' the fringe belt into two. Limassol is now a significantly large city and the urban area encompasses the former villages to the north of the motorway; despite the densification, large gaps and large blocks remain in the urban fabric, especially within the fringe belts and the distribution of the population between the urban and the metropolitan areas has continued to decrease towards lower densities from 70% of the population based in the urban area in 1982 to only 52% nowadays (Gerasimou and Georgoudis, 2011) due to suburban sprawl and the proliferation of private parking space, while employment, services and commercial activities as well as tourist services concentrate in the historic town centre and the coastal area.

Methodology

Two types of analyses were undertaken to describe and analyse the evolution of the urban form of Limassol: space syntax analysis and block size analysis. Both were applied to all the available historical maps and were selected not only because they provide quantitative results

which in a later phase of research can be statistically related to social data, but also because they are particularly suitable to diachronic analysis and applicable to the city scale with relatively little human and time resources. Space syntax methodology provides an analysis of the city at different scales and has the ability to highlight how the main structure of the city changes over time, while block size analysis is able to capture and describe the process of formation and densification of fringe belts as described by Whitehand (2001) and M. P. Conzen (2009). Both methodologies are highly relevant to the case at hand: space syntax because it allows for comparison of systems of different size and is thus a reliable hard measure for comparing a city diachronically when this has grown significantly, as is the case here; block size analysis provides a 'proxy' - if only very limited - for a Conzenian approach by assessing changes at street block level. In the case of Limassol, where the initial assessment of its form and development clearly shows the existence of an inner, middle and outer fringe belt, it is necessary to engage such a methodology and assess the fringe belts individually along with the spatial analysis.

Six spatial models of Limassol were constructed using space syntax methodology⁶⁷. Space syntax quantitatively describes patterns of spatial layout; once the model is built, it can be analysed to provide various measures reflecting different properties of the urban configuration and of specific elements of the street network, such as a street segment. The most important measures of space syntax are *integration*, representing 'to-movement' or the accessibility of a specific element within the system, and *choice*, representing 'through-movement' or betweenness (the number of times a segment falls on the shortest route between all pairs of segments within a specified radius). Measures can be calculated at the city-wide scale or at any given radius, the city-wide measures taking into account all elements in the system and the 'local' measures taking into account all elements within the given radius. City-wide measures tend to be representative of the whole-city structure and often correlate with vehicular movement; local measures tend to be representative of local neighbourhood structures within a city and often correlate with pedestrian movement.

The specific analysis used in this study is angular segment analysis, which takes into account least angular deviation of each segment from all other segments (hence it takes into account the relative straightness of a route). The measure used is *normalised angular choice* (referred to here as NACH, 'choice' or 'accessibility') which allows for comparison between systems of different size. Furthermore because of the mathematical way the measure of choice is normalised, it takes into account the depth of elements within the system (a proxy for integration) and hence it combines a representation of to- and through-movement (see Hillier et al. 2012).

NACH values range between 0 and 2, where values above 1.3 are considered to be in the top range of accessibility, and values of 1.5 or above being extremely high. All the segments in the system with values of 1.3 or above are considered here to be part of the core structure of the city – the global structure when considering the whole system or the local neighbourhoods' structure when considering a specific local radius. The two cores can be matched to identify the *multi-scale* core of the city – all the segments which have both the highest global and local integration value, constituting the centrality of the city.

The spatial models were drawn manually in MapInfo GIS using historical and contemporary maps as basemaps, which were geo-referenced manually using 10 control points. The contemporary spatial model was constructed first, layered onto the historical maps and elements removed and adjusted to construct the historical models with a methodology similar to that of Pinho and Oliveira (2009). The choice measures were calculated using the DephMap Process tool in the Space Syntax extension for MapInfo developed and licensed by Space Syntax Ltd.

⁶⁷ For further details of space syntax theory and methodology see www.spacesyntax.org along with Hillier and Hanson (1984); Hillier (1996); the appendix in Vaughan and Geddes (2009) for details of space syntax measures, Hillier and Iida (2005) for details of angular analysis, Hillier et al. (2012) for details of the normalised choice measure, and Versluis (2013) for details of multi-scale analysis.

NACH was then calculated automatically in GIS using the formula provided in Hillier et al. (2012).

Block size maps were automatically constructed from the spatial model using the Blocks Size tool in the Space Syntax extension for MapInfo mentioned above. Average block sizes were calculated for the whole city, the historical core and each fringe belt using simple query tools in GIS. It must be stressed that this is only a very limited 'proxy' for the Conzenian approach as the automated way of constructing the blocks, though time efficient, means that these comprise the open areas and not just the built blocks; it also means that blocks at the edges of the model which are not bounded by roads and accessed through a dead end are not represented in these maps. The areas were defined as follows:

Historical core: from the coast line to the route along Navarinou/Gladstonos, comprising the historical Turkish area to the west of the river and the public gardens on the east side of the town centre. This comprises almost all of the built area of 1883;

Inner Fringe Belt (IFB): the area comprised between the route along Navarinou/Gladstonos and the inner ring road (Makariou), including the industrial area to the west up to the new port, for the years 1933, 1960, 1987, 2003 and 2011;

Middle Fringe Belt (MFB): the area comprised between Makariou and the A1 motorway for the years 1960, 1987, 2003 and 2011. This was divided into Middle Fringe Belt A (MFBa), the area comprised between Makariou and the outer ring road built in the 1990s, along the road of Kyprianou comprising the area of Agios Nikolaos to the east and Tsiflikoudia to the West, and Middle Fringe Belt B (MFBb), the area comprised between the edge MFBa and the A1 motorway. MFBa and MFBb were used in the analysis of 2003 and 2011;

Outer Fringe Belt (OFB), the area outside the A1 motorway comprising the old villages surrounding the city and also including the tourist area, the easternmost stretch of city along the coast within the motorway for the years 1987, 2003 and 2011.

Findings

Spatial analysis

The space syntax analysis shows that the greatest change over time occurred in the 'superstructure' of the city, with global accessibility values decreasing steadily through the years for both the city as a whole and the historical town centre. This decrease is slightly more pronounced for the city as a whole – a significant drop occurred between 1883 and 1933, but this is perhaps because the spatial model of 1933 includes the footpaths radiating out to the surrounding villages and at the time few connections between the radial routes were available outside the town centre.

The greatest drop in the global accessibility of the town centre comes between 1960 and 1987, hence following the construction of the motorway.

At the local level, whether this is very local (400m) or a slightly wider radius (1200m), change is not as significant, in particular following 1960s, values of local accessibility for both the historical town centre and the city as a whole seem to stabilise, especially for the wider local accessibility at 800m and 1200m radius. The results of the space syntax analysis are summarised in table 1.

The global structure of the city shifts from the historical centre outwards, initially it comprises all major routes within the centre including the whole of the seafront, the street of Agiou Andreou and the whole of Anexartisias. By 1960 the western side of the seafront has lost its importance at the city-scale and the global structure includes less segments within the historical centre and more to its north, including much of the inner ring road (Makariou). By 2011 only the northern edge of the historical centre is part of the global structure of the city, which has moved further north and east to comprises both ring roads, the motorway and most of

the radial roads, including the stretches going through the old villages and the stretch of the seafront east of the inner ring road, leading to the tourist area along the coast.

Table 1. Mean accessibility values

Year	Town Centre R400	Town Centre R800	Town Centre R1200	Town Centre RN	Whole City R400	Whole City R800	Whole City R1200	Whole City RN
1883	1.10	1.13	1.16	1.26	1.10	1.13	1.14	1.24
1933	1.13	1.15	1.19	1.24	1.15	1.19	1.19	1.15
1960	1.14	1.16	1.19	1.20	1.10	1.12	1.14	1.11
1987	1.14	1.16	1.18	1.11	1.08	1.09	1.10	1.03
2003	1.13	1.16	1.18	1.09	1.08	1.09	1.10	1.03
2011	1.14	1.16	1.18	1.10	1.09	1.09	1.10	1.02

The distribution of local accessibility values at the 1200m radius changes far less over time and although accessibility decreases slightly in the southern area of the city and increases in the area north of the historical centre, the difference is not significant, suggesting that the development of the city to the north and the changes occurred over time have only had a marginal impact on the functioning of the historical town centre at the local level.

The results of the multi-scale analysis, measuring the overlap of street segments with both high global accessibility values and high local accessibility values, clearly shows how the core structure of the city shifts overtime – this is presented in figures 5-10.

The overlap between global and local accessibility is an indicator of the intelligibility of a city. The extent of the overlap was measured as the proportion of segments with both global and local (1200m radius) NACH values of over 1.3 out of the total number of segments. This analysis (presented in table 2) shows that except for 1883 when the city was still fairly small and much of its eastern side made up of open fields and gardens, the overall extent of the multi-scale core decreases significantly over time. It also shows that the core concentrates in the historical town centre. As the core shifted towards newly built areas in the city the difference between the extent of the core within the town centre and within the whole city also decreases significantly as more and more of the core ‘moves’ out of the historical town centre – the exception again is 1883 when almost the whole city was within the boundary of the historical core. It has to be noted however that, despite dramatic growth and change a good proportion of the historical centre is still part of the core, though most of this is its northern edge (figure 10).

Table 2. Extent of multi-scale core

Year	Town Centre	Whole City	Difference
1883	25.2%	22.6%	2.6%
1933	33.6%	18.7%	14.9%
1960	27.3%	14.7%	12.6%
1987	19.2%	6.9%	12.3%
2003	15.0%	6.0%	9%
2011	10.2%	5.0%	5.2%

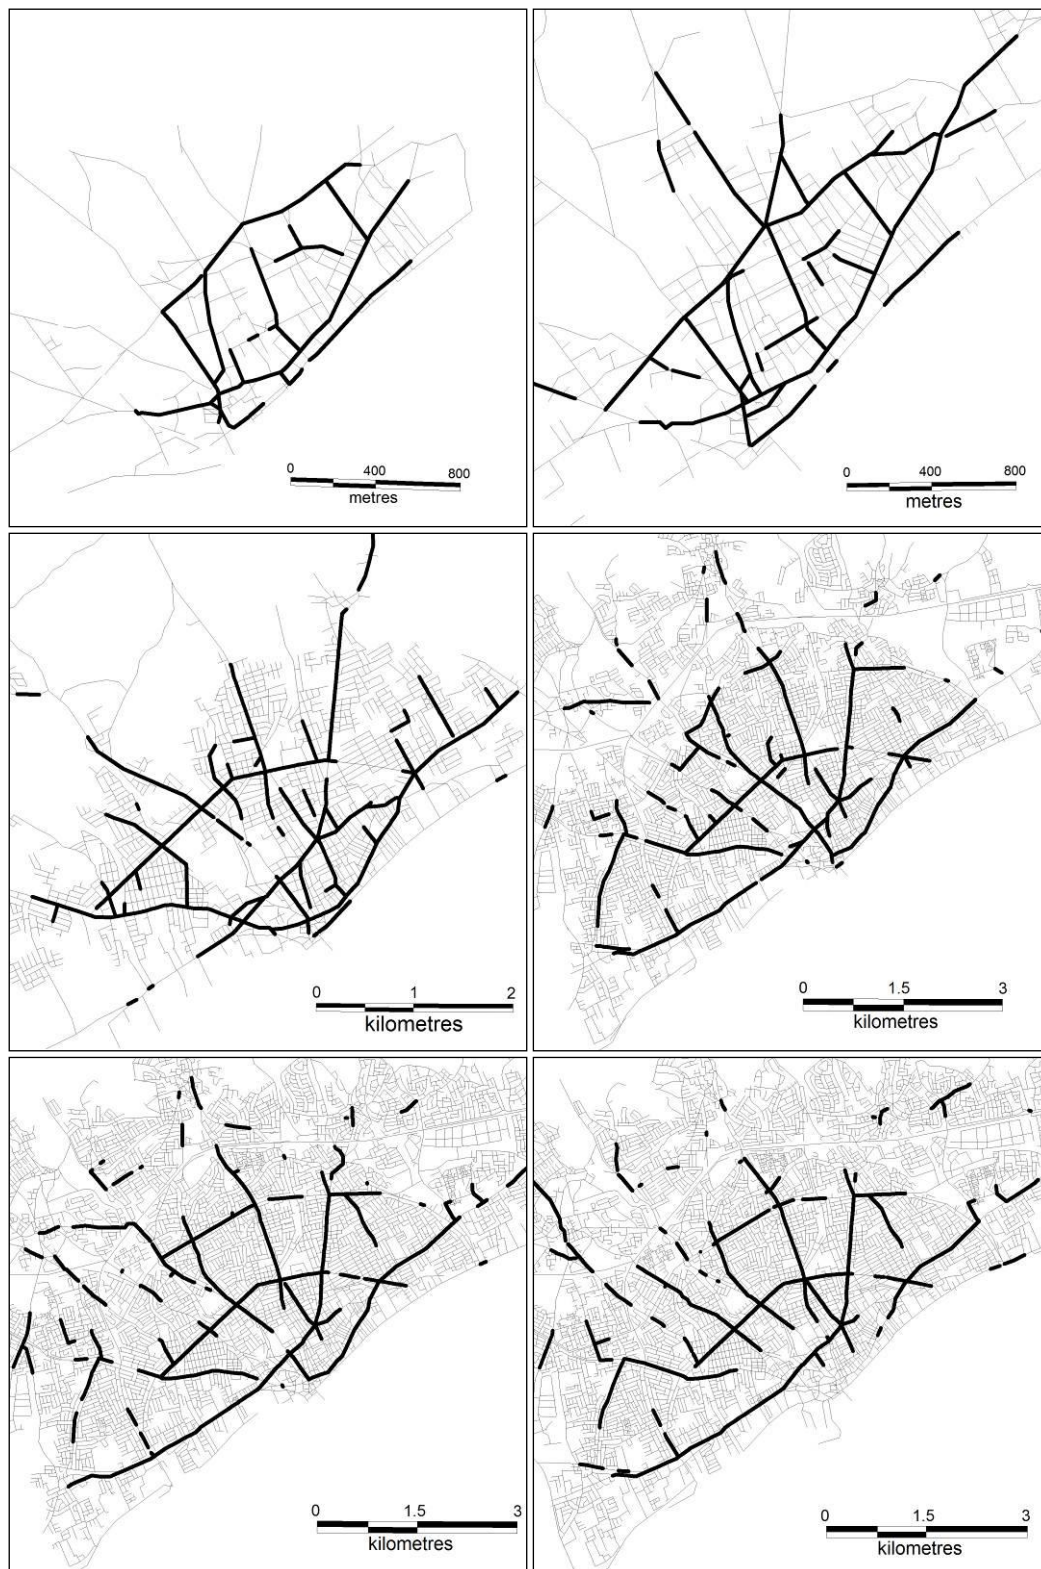

Figure 5. Multi-scale accessibility core of Limassol (left to right and top to bottom: 1883, 1933, 1960, 1987, 2003 and 2011).

Block size analysis

The block size analysis of the contemporary city (figure 6) shows how the historical town centre is almost wholly made up of small blocks with the exclusion of the eastern edge where the athletic centre and public gardens are located, and the western edge where a newly-built marina has created a number of large blocks. Both the IFB and MFBa are also dense with some exceptions, especially at their western end along the coast where much of the industrial uses are still located.

MFBb still comprises a high number of large blocks, especially in the eastern side where a large industrial area is located and residential development is still very low density. In this case the areas dense with very small blocks comprise many of the refugee housing estates built after 1974, which are made up of slab building blocks criss-crossed by a high number of pedestrian footways creating highly permeable environments and very small street blocks. This area also includes the centre of the old village of Mesa Geitonia – the only one to the south of the motorway. The OFB comprises the highest number of very large blocks, including along the coast to the east where the tourist development has seen the construction of large hotels with extensive grounds and parking areas; the dense areas to the north of the motorway are the centre of the old villages surrounding Limassol.

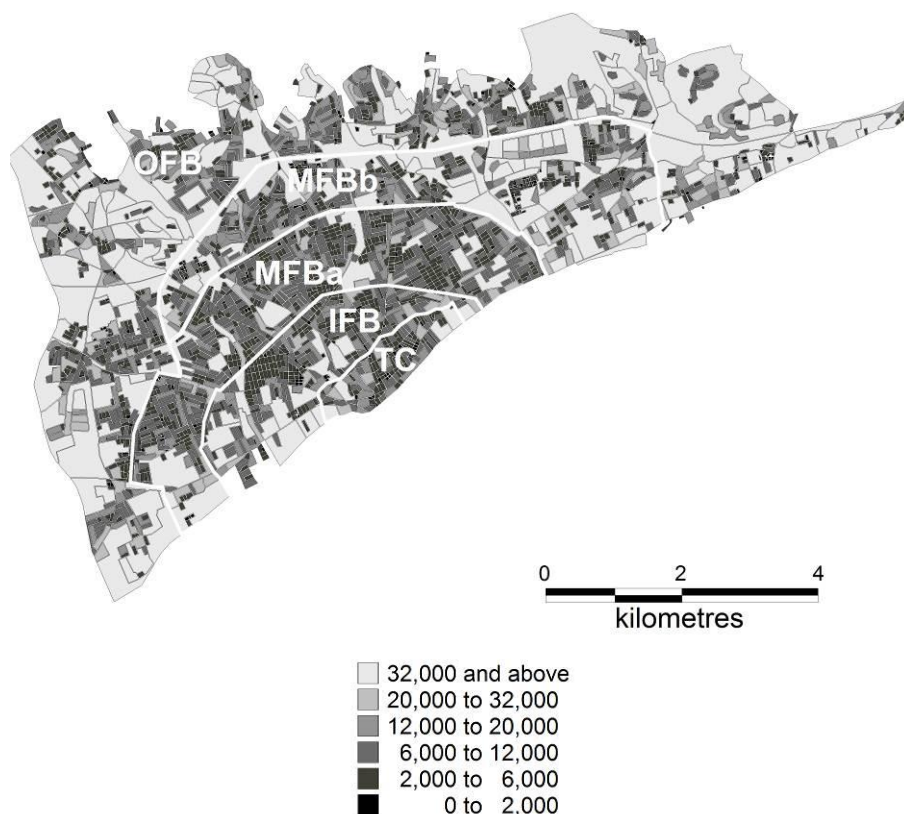

Figure 6. Block size (m²) map of Limassol, 2011.

Looking at the distribution of block sizes over time (table 3), it is interesting to note the fluctuation in the proportion of large block sizes (20Km² – 32Km² and 32Km² and above) which increases as fringe belts are created (IFB created 1883-1960), decreases as they are densified (IFB densified, beginning of MFB 1933-1960), increases again as further fringe belts are

created (MFB established, OFB created 1960-1987), decreases again as the fringe belts are further developed (IFB, MFB – in particular MFBa – and OFB densified 1987-2003) and increases again as the OFB expands farther (2003-2011).

Table 3. Distribution of block sizes over time

Size (Km ²)	1883	1933	1960	1987	2003	2011
32+	7.5%	14.8%	4.1%	5.9%	5.5%	6.7%
20 - 32	5.3%	5.6%	2.4%	3.6%	4.4%	4.7%

The mean block size for each area over time shows the densification process occurring across time in all areas (table 4), this is with the exception of the city as whole which expanded greatly between 1883 and 1960 to develop two fringe belts. The block size for the town centre, the OFB and the city as a whole also increased between 2003 and 2011, in the former case this is due to the marina development at the western edge of the historical town centre which has created large blocks where previously there were none, in the latter two cases this is due to the expansion of the OFB further out into the surrounding areas. It should also be noted that once the MFB gets split into two it is the northern part, further away from the town centre that comprises the large blocks (slightly larger on average than for the whole MFB 15 years previously. Interestingly, the MFBa has smaller blocks than the IFB, this is possibly because the IFB has retained many of its former land uses which require large blocks, while the MFBa has been the focus of much residential development.

Table 4. Mean block size (m²) for each area

Area	1883	1933 ⁶⁸	1960	1987	2003	2011
Town Centre	9,810	9,675	7,211	6,879	6,374	7,104
IFB	29,404	78,051	14,464	10,166	9,625	9,407
MFB			15,039	14,268	11,103	10,697
MFBa					8,788	8,547
MFBb					14,631	13,617
OFB				18,680	15,074	19,963
Whole City	11,269	87,924	15,786	14,134	11,927	13,548

Discussion

Shifting centrality, spatial change and continuity

The fact that global accessibility continues to decrease despite the insertion of ring roads across the city suggests that such roads, thought of as improving longer distance connectivity within

⁶⁸ The value for the IFB and the whole city in 1933 comprise a large area of open fields between the historical town centre and the surrounding villages included in the spatial model and it is thus not comparable to the other values.

the city, either do not meet this purpose or do not do so sufficiently to ‘counteract’ the effect of growth, densification and sprawl on global accessibility.

It is perhaps to be expected that local accessibility values of the historical town centre would change little after a certain time, as development and redevelopment would occur mostly in areas relatively far from it. This is however only partly true as a major development recently occurred within the historical town centre with the construction of the new marina – this has clearly impacted on the mean block size of this area, but does not seem to have had a measurable impact on accessibility, which may also be due to the fact that it is located along an edge of the city (the coastline).

It is certainly more puzzling why at the city wide scale local accessibility values seem to remain quite stable despite a lot of densification and change in permeability as shown by the block size analysis. This might be simply an effect of averaging local values for the whole city, whereas changes might be found within local areas subject to development between two periods, or it may be that somehow the system ‘adjusts’ itself over time to provide a certain level of overall local accessibility across different areas. This issue remains open for further analysis and interpretation.

Centrality has been shown to be a process (Hillier, 1999) and it is certainly not surprising that this has shifted over time to ‘relocate’ to a more geographically central area with characterised by higher accessibility. The decrease in global values and in the extent of the multi-scale core was also to be expected as this is in line with previous research showing that global accessibility and legibility tend to decrease over time as the city-system grows, and that this is the case for many Mediterranean port cities that have grown rapidly in recent years (Shpuza, 2009). The shift in centrality shown by the spatial analysis is corroborated by historical records and contemporary data on land use which identify the main commercial road as moving from Agkyras at the western edge of the town centre to Agiou Andreou further east and then northwards onto Anexartisias and Makariou, the latter three remain popular commercial streets, with Agiou Andreou being more of a tourists’ destination and Anexartisias and Makariou being more of a locals’ destination.

The fact that a good proportion of the town centre is still part of the multi-scale core of the city points to a form of ‘spatial resilience’ of the historical centre in the face of dramatic growth and change.

Fringe belt formation, expansion and densification

The block size analysis shows that fringe belts with different characteristics and varying mean block size do exist. These are created through the establishment of long, fairly continuous ring roads, but are ‘broken up’ into areas by radial routes, many of which correspond to former footpaths leading to surrounding villages. Densification of each area over time is also clear and this has occurred through the creation of shorter streets (often of equal length with many residential areas having grid-like design) as part of developments built within the boundaries of the areas formed by the long radial and concentric routes. The analysis however also shows that densification is not necessarily an infinite and irreversible process as the rate of densification tends to decrease over time and may eventually come to a halt. In the case of OFBs this may, at least temporarily, develop to be less dense through expansion into surrounding areas, while specific cases, such as that of the town centre where the construction of the marina has seen the creation of a land bank along the coast and the formation of large blocks, means that even when block size is traditionally small and persistently so, development interventions may alter the picture of the historical urban form.

Conclusions

This paper has brought together two types of analyses to reveal trends in the evolution of the urban form of Limassol. Additionally to confirming previous research results regarding decreasing global accessibility and intelligibility of cities through growth and development, and the formation and ‘internalisation’ of fringe belts over time, it has highlighted the resilience of the Limassol’s historical town centre as a successful local centre at various local scales. It has also pointed to the interrelationship between the construction of long concentric routes, the formation of fringe belts and accessibility values at the global and local level by revealing that roads planned for improving long-distance connections within a city may not have the impact they were expected to, do not necessarily influence the functioning of local neighbourhoods and might in some cases (such as in the case of the eastern stretch of Makariou) turn into local centres themselves. Without diachronic analysis it would not have been possible to assess how the addition of physical elements to the existing systems had an impact on the way the city functions at present, neither it would have been possible without assessing both the spatial accessibility of the city and the process of densification together.

The combination of space syntax and Conzenian approaches used here contributes to the development of the links between the two and the further understanding of their complementary which has been initiated in recent years (Pinho and Oliveira, 2009; Griffiths et al., 2010). The large time gaps between the maps analysed and the lack of detailed information about the planning, approval and construction of specific physical elements of the city, does not, unfortunately, allow for an accurate analysis of the economic cycles which are a pre-requisite for the emergence of fringe belts along with the existence of an established urban core. Both these elements do certainly exist in the case of Limassol, however the time gap between the periods analysed includes both times of economic slump and growth and they do, in fact, cover both the establishment of long routes and fringe belts as well as the construction of shorter routes, formation of smaller block sizes and densification of fringe belts. Perhaps the most important result of this study is that it opens up possibilities to enhance the understanding of generative rules of development by further researching the relationship between the economic cycles and the times of construction of longer and shorter routes along with the analysis of street blocks, hence shedding light on how the space syntax’ laws of centrality and compactness (Hillier, 2002) relate to fringe belt theory and economic trends.

Analyzing the effects of hot and arid climate on the form of historic cities of Iran

Seyed Abdolhadi Daneshpour, Mohammad Rezai Nedoushan, Aliakbar Sardareh

Department of urban planning and design, School of Architecture & Environmental Design in IUST. Email: daneshpour@iust.ac.ir, rezainedoushan@iust.ac.ir, alisardareh@iust.ac.ir

Abstract. *A significant portion of the current territory of Iran is situated in hot and arid climate. While the strenuous climatic conditions have made living very trying, the greatest and biggest cities of Iran in the last millennium have emerged in these areas. It seems that one of the reasons contributing to the formation, growth and sustainability of these cities, is the specific methods used in their architecture and urban planning. Since one of the methods has manifested itself in the form of historic cities in hot and arid climate, in this paper urban form is analyzed. The main focus in analysis of urban form is urban structure (shape, figure, direction of passages), neighborhood context (shape, size, direction, sort of buildings and yards) and mass and space patterns. The aim of this paper is to assess the urban form in order to discern the characteristics whose make the harmony between urban settlement and harsh climatic conditions. Results of this survey are shown that special form of historic cities (Qazvin, Qom, Kashan, Nain, Yazd, Kerman, Meybod and Ardakan) was affected by Climate property. Moreover the special climatic characteristics of each of these cities make a difference in their form characteristics to achieve appropriate compatibility with environment.*

Key Words: Form characteristics, hot and arid climate, historic cities of Iran

Introduction

Archeological discoveries have shown a history of 8000 years of urbanization in Iranian plateau. Vast alluvial plains, groundwater resources and having knowledge about agriculture, mathematics and astronomy has helped to foundation and survival of different civilizations in the central Iranian plateau. Today, because of last millenniums climate changes, approximately all parts of Iranian plateau have hot and dry climate which is an unsuitable condition for human living. Iranians have applied different techniques to survive and live in this condition. Application of these techniques can be seen in the urban form of Iranian historical cities. Iranian large cities generally have hot and dry climate and their fabrics are effectively related to their surrounding environment.

Therefore, in this paper the general climatic condition of central Iranian plateau is presented at first and then, those characteristics of urban form that were the result of this climatic condition are listed. Study of urban form in this paper is more based on the work of Conzen. Structure of city (form and orientation of roads) and neighborhood fabric (form, size, orientation and arrangement of buildings and open spaces, built form and open spaces patterns) are considered in the investigation of urban form. The quality of relationship between climate and urban form in Iranian cities will be examined in the next sections.

Iran hot and arid climate

Central, eastern, southeastern and southern regions of Iran have hot and dry climate. Hot and dry climate in central Iranian plateau is dependent on two phenomena. First, the Hedley cell phenomenon (figure 1) and the second, its location on the world's desert belt and also being

surrounded by Alborz, Zagros and Hindukush mountains in north, west and east, which prevent moisture advection over inland parts (figure 2).

Figure 1. Hedley cell phenomenon⁶⁹.

Dasht-e Kavir and Lut desert are two large and inhabitable deserts in the world that are located in central Iran. Foothills of the Alborz and Zagros mountains are habitable areas of central plateau. From Qazvin in northwest to Sistan in southeast, there is a chain of settlements located in the margins of desert. This chain of settlements consists of different large and small cities and villages. Large cities in the mentioned region, from northwest to southeast, are Qazvin, Tehran, Rey, Qom, Ardestan, Nain, Ardakan, Meybod, Yazd, Bafq, Sirjan, Kerman and BAM. Among them, those cities that have preserved their traditional fabrics are selected and investigated in this paper.

Figure 2. Iran climate zones, cities located in hot dry climate⁷⁰.

The mentioned cities are surrounded by Zagros Mountains in west and vast deserts in east. This geographical condition causes favorable wind from west and unfavorable wind from east.

⁶⁹ <http://fanack.com/en/countries/iran/basic-facts/geography-and-climate/biodiversity>

⁷⁰ <http://askabiologist.asu.edu/explore/desert>

Iranian cities were established in regions with sufficient water resources. There are two kinds of water supply: springs, like Fin spring; and Qanat systems which transfer melt water from mountains to human settlements. Dry weather in these cities causes big temperature differences between day and night, summer and winter. In summers, temperature goes high up to 40°C and in winter, there are several ice days. Temperature difference between day and night, particularly at first days of spring and fall is approximately 20°C.

Figure 3. Wind flow in the cities located along desert margins, hot dry wind from east and cold humid mountain wind from west.

This extreme weather condition has always challenged living of people but also has led them to find amazing solutions in competing annoying weather condition. They have learned to exploit this weather condition to create comfortable condition for living. These hard weather conditions are: the scorching heat of the sun; high temperature in day and low temperature at night; diurnal temperature variation particularly in summers; extreme cold weather in winter and extreme hot weather in summer; dry weather as a result of little precipitation and water supply reduction; occurrence of hot storms with dust and sandy tones.

The urban form of desert towns

Structure and fabric of desert towns are investigated in this paper. Structure is about the shape of street network. Shape of street network, hierarchy of roads, length and width of roads and their junctions are studied in the structure section. The study of urban fabric is done in two scales: shape and size of blocks and shape and size of parcels. Parcel Shape, parcel orientation, compactness, arrangement of parcels, proportion of built forms to open spaces, density and orientation of open spaces are studied under the subject of urban fabric.

Figure 4. Relationship of urban form characteristics in Iranian historical cities.

Structure

The hierarchal order of street network including Main Roads, alleys lead to neighborhood centers (Gozar), secondary alleys (kocheh), semi private passageways (Darband), is most

important characteristic of urban structure. These Roads are different in length, width, orientation and other qualities. Alleys that lead to neighborhood centers are wider and their orientation is northeast southeast. All these kinds of roads have the same orientation, but there are some exceptions in Kerman and Ardakan. These exceptions will be discussed in the next section. Alleys that lead to neighborhood centers are main roads in formation of the historical urban structure. Secondary alleys are perpendicular to main alleys and connect one main alley to another one. Semi-private passageways are branches of alleys that are meandrous and covered in some parts. (Rezai, 2009)

Figure 5. Hierarchical order of roads in Godal mosalla neighborhood of Yazd, orientation of main alleys are similar to the orientation of houses (Rezai 2009).

Street network is generally organic. It means that they don't have ordered geometric shape, but they have structured in a natural order. Shape of roads is based on the land topography. Roads are generally established in place of gullies. None of traditional cities have Euclidean geometry in shape of street network, but they have organic form. They were very narrow in comparison with today's streets. In fact, they were tracks among urban blocks.

Figure 6. Fabrics of Isfahan, Qom and Meybod, urban roads are tracks among dense urban tissues. Wide and straight streets are the result of interventions in last centuries.

Urban fabric

This section investigates size, shape, arrangement of urban blocks and parcels which is based on property boundaries. Shape and patterns of built forms and open spaces are also considered.

Urban blocks

Urban blocks are set of cells separated by roads. They have organic shape like human body's cells. They seem disordered in comparison with modern urban fabrics, but they have organic order. Blocks are not equal in size, but they can be classified in certain ranges. Blocks are arranged in coherent and connected urban fabric. As mentioned above, narrow alleys separate blocks in compact fabric of traditional cities.

Figure 7. Blocks arrangement in historical cities of Iran.

Shape and size of parcels

Parcels are located in compact fabric and they don't have certain geometric shape. They are in large and small size. Their orientation is coordinated with alleys orientation, that is northeast southwest toward Qibla.

Figure 8. Blocks arrangement in Yazd and Qom.

Built form and open spaces

This section investigates the proportion of built form to open spaces in urban parcels. In historical cities, houses have central courtyard and built forms were arranged around the central courtyard. Therefore, in study of urban form of Iranian historical cities, the built form contains living spaces built around one open space (central courtyard). Unlike the shape of whole parcel, the central courtyards have certain geometric shapes. Orientation of all courtyards in one city follows same pattern.

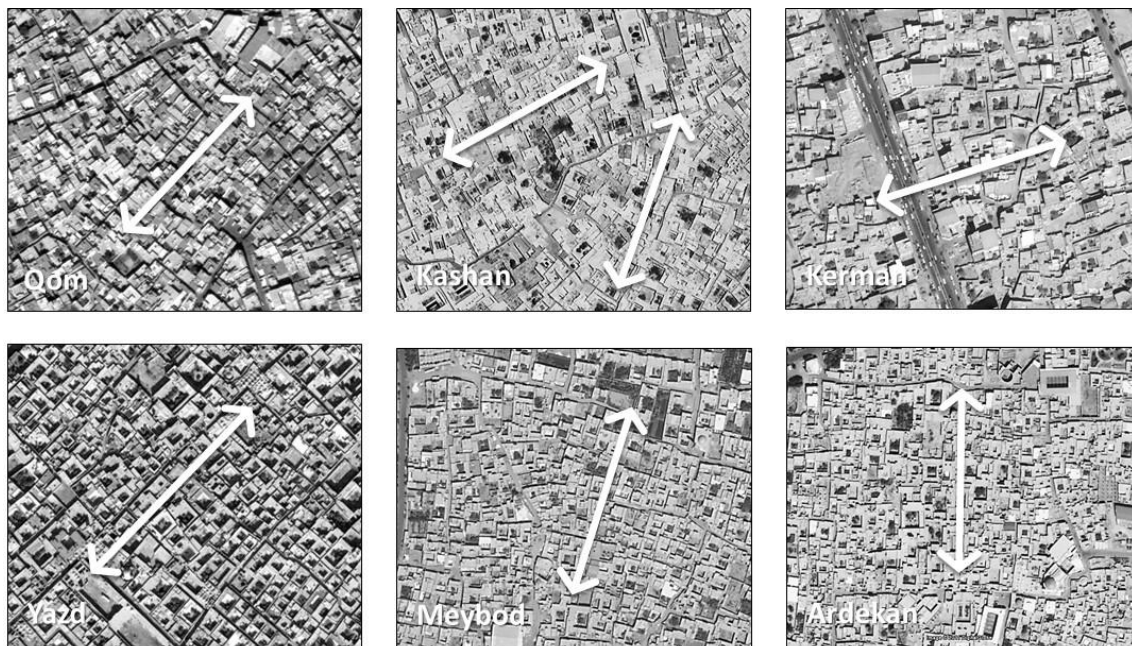

Figure 9. Orientation of courtyards in Iranian historical cities.

Urban form and climate

Urban form of Iranian historical cities were discussed in the previous section. In this section, those characteristics of urban form will be discussed that make historical cities more compatible with the microclimate of their region. These characteristics can be observed in the structure and fabric of historical cities. Those people living in similar climatic condition have similar problems.

Orientation of roads

In almost all Iranian cities, orientation of alleys that lead to neighborhood centers is toward Qibla, northeast-southwest. This orientation is the same as orientation of houses and in accordance with central courtyard which makes traditional houses more energy efficient. This is also the best orientation to get benefits of favorable winds. Ardakan and Kerman are exceptions to this principle. Alleys leading to neighborhood centers are in north-south orientation in Ardakan and in east-west orientation in Kerman. This is because of different direction of favorable winds in these two cities. In Ardakan, mountains are located in south of the city and therefore favorable wind blows from south to urban area. In Kerman, elevated mountains are located in east and wind blows from east to west.

Figure 10. Urban roads in Yazd, Ardakan and Kerman, Alleys leading to neighborhood centers are in north-south orientation in Ardakan and in east-west orientation in Kerman.

Narrow roads are another feature of urban form that help these cities encounter extreme climatic condition. This narrow width increases compactness and help to encounter unfavorable winds. Elevated walls shade narrow road's area and help to protect from direct sunlight heat. Covered spaces of alleys increase shaded area. Being covered and having large height to width ratio make these spaces more comfortable in the presence of hot dry wind of desert regions. One important characteristic of urban form is compactness. Compactness will be discussed in the next section.

Compactness

Compactness help to protect from unfavorable hot dry winds in summer and cold dry winds in winter. Compactness also decreases heat absorption from sunlight. Compactness protects building walls from sunlight in summer and form cold airflow in winter. One of most valuable solutions in response to extreme climatic condition of Iranian historical cities is the reduction of the amount of area exposed to heat by increasing compactness.

Central courtyard

Central courtyard plan of houses is most important characteristic of urban form in all Iranian historical cities. This pattern is a specific feature of historical Iranian urban form. All building parcels have central courtyard and unlike the shape of whole parcel, they have ordered shape and similar orientation. This ordered shape and similar orientation is completely consistent with the climate of their regions.

Figure 11. Shade and light patterns in central courtyard houses in morning, noon and evening time.

Figure 12. Northeast-southwest orientation of courtyards in Yazd.

Courtyards are generally in rectangular shape. Elongation of courtyards has northeast-southwest orientation. This elongation allows maximum use of sunlight for east and south side of the house. This elongation also allows maximum use of favorable sunlight in morning time. Axis of this elongation is also oriented toward Qibla. As mentioned above, Kerman and Ardakan are the exceptions to this principle.

Built forms including rooms, halls and porches are arranged around central courtyard. This kind of spatial arrangement allows the use of natural light in living rooms. Small size of rooms makes them more energy efficient and cause reduction in energy consumption for cooling and heating.

Figure 13. Arabs house in Yazd, Functionality of architectural components and the climate. (Tavassoli 2002).

By being lower than ground level, courtyards are able to preserve cold air mass of early morning hours in the yard and apply it to keep the house spaces cool in next hours. Houses with Godal Baghche, a green space lower than ground level, more effectively do this. Long courtyards have shade in morning and evening due to smaller angle of sun's rays. Airflow over the building parcel does not whirl dust particles that are near the garden surface and therefore dust particles cannot enter the living rooms.

Figure 14. Ordered rectangular shape of central courtyards unlike the organically shape roads in Yazd (Rezai 2009).

Conclusion

Climatic condition has always challenged the living of people in central parts of Iranian plateau. This has led them to find amazing solutions in competing annoying weather condition. They have learned to exploit this weather condition to create comfortable condition for living. These cities with narrow roads, compact fabric, appropriate built form and open space patterns, have created comfortable space for their settlers. This study showed that the orientation of roads, shape and size of blocks and parcels in Iranian historical cities were cleverly designed in relation to the climatic condition of their region. Urban form of Iranian historical city had made the living of its settlers more sustainable and allowed them to efficiently get benefits of natural resources. However, modern urban form of Iranian cities is not like historical urban form and their settlers consume a large amount of resources and energy in their life. It seem that thousands years of experience in shaping urban fabrics is dismissed. Iranian historical cities were in complete harmony with their natural environment like a bird nest or termites construction.

Island-City / City-Island: Island precincts and evolving urban morphology of Abu Dhabi, UAE

Anamika Mishra

Department of Architecture and Design, College of Engineering,
Abu Dhabi University, Abu Dhabi, PO Box 59911. E-mail:
Anamika.Mishra@adu.ac.ae.

Abstract. *Islands hold a strong association with concepts of exclusivity and nature, due to their isolated configuration and the strong presence of the Sea, respectively. However, examples abound of cities that have emerged as island cities and as urban archipelagos. Consumerist and tourism-driven economies have helped further appreciate the value of the islands waterfronts and their adaptation as landscapes of leisure and recreation. Advances in technology and availability of capital have allowed articulation of grand visions for islands, both natural and man-made. Hence the development of islands has played a significant role in the emerging urban form of several coastal cities. Cities in the Middle East, in particular, have displayed this pattern in a more pronounced manner and as a recurring theme, evident in projects like The Pearl-Qatar and The Palm Islands (Elsheshtawy, 2010), which have also contributed to the city-image of Doha and Dubai respectively. Abu Dhabi, an island city itself, has joined this trend by recognizing the development potential of its peripheral islands. While historically development was concentrated on the main island, which characterised the city form, it has now extended to the various peripheral islands that are being developed as key projects. This paper studies the emergent morphology of Abu Dhabi, as influenced by the creation, development and redevelopment of its various islands. Common morphological patterns at the scale of the island shall be identified and relations drawn to the overall city morphology. The paper also discusses issues pertaining to the evolving city morphology such as the environment, connectivity, edges, seams and gateways.*

Key Words: *Abu Dhabi, Islands, Morphology, Urban form, Urban design.*

Cities, due to their inherent definition as places of concentration and exchange, have constantly grappled with the pressure to grow and expand which in turn has triggered urban transformations that mark the morphological history of the city. City form has been shaped by the primary layer of the city - its natural geographical and topographical condition - 'the constitution of the elements, land and water, nature, soil and climate' (Le Corbusier, 1957). Coastal cities, urban waterfronts, hillside towns, bayside development are all examples of urban types which reflect this interplay between the natural layer of the city and the development pressures it experiences. This paper explores the emerging urban patterns relating to city form through the development of its peripheral islands by providing an account of the city of Abu Dhabi, the capital of the United Arab Emirates.

The case of Abu Dhabi is particularly interesting, since it is representative of several characteristics observed in many of the Gulf cities – accelerated growth due to discovery of oil, focused efforts at diversifying the economic base, particularly through the tourism sector, intense inter-city competition and assertion as world-cities. In addition to commonalities in climate and culture, the cities also share a common regional geography that includes a barrier island chain along the coast. Water, as a landscape feature, finds a special importance in new developments. Cities like Dubai, Qatar and Bahrain are constructing a new city image through high-profile projects like the Pearl Island reclamation project in Doha and the Palms Islands in Dubai. The region has also received considerable attention with regard to sustainability, primarily because of the rapid economic growth driven by fossil fuels, extreme climatic conditions that necessitate widespread use of air conditioning and the requirement for desalination plants. The Gulf countries wanting to position themselves towards sustainable

growth due to high per capita emissions, have been undertaking several initiatives such as Qatar Sustainability Assessment System (QSAS) in Qatar and Estidama in Abu Dhabi to demonstrate their commitment towards this cause.

In order to create a background for the contemporary urban form, this paper first presents a brief development history of the city. The plan 2030 and current development proposals are then comprehensively described. The paper examines the current and future patterns of development that relate to the decision to develop the peripheral islands. The research methodology includes site visits and an examination of the physical attributes of different areas. Morphological studies are used to discuss these patterns and to investigate the relation of elements, both at the scale of the island as well as the city. Select examples have been discussed as cases that are particularly illustrative of the issue and to substantiate the conclusions that are being drawn. The paper concludes with a consideration of the emerging issues relating to the urban form and summarizes potential future directions.

Helmy (2008) in her doctoral dissertation provides a summary of urban studies in the Gulf and categorizes them as historical urbanization, modern urbanization and oil urbanization. Contemporary research in the post-oil urban fabric has been faced with the challenge of keeping pace with the explosive growth experienced by the Gulf countries. Elsheshtawy (2005, 2010), Moustafa (2005), Eleishe (2006) and Al Naem (2005) have discussed aspects of contemporary urbanism in various Gulf cities. This paper attempts to contribute towards the body of research in the post-oil urban fabric of Abu Dhabi by discussing a contemporary urban pattern that addresses the role of environment in shaping the urban fabric.

Abu Dhabi – A brief history

Abu Dhabi is the capital of the United Arab Emirates, the seat of the federal government and the wealthiest of the Emirates as a result of its abundant oil reserves. It is situated on a T-shaped island which projects into the Arabian Gulf from the central western coast, a part of an archipelago of several islands within the emirate. Other islands, such as Sir Bani Yas and Dalma have played a historical role in the evolution and growth of the southern Arabian Gulf as a trading center. In general, the native people of the Gulf region, called the Bedouins selected areas such as the mountains, oases and the coast while seeking settlements in the harsh desert conditions. The largely nomadic, migratory population shifted from region to region in response to the rhythms of seasons and trade. Buildings and settlements were distributed along a net of social and economic relations that tied the interior of Arabia with the larger commercial network of the region (Hawker, 2008).

Residential clusters date back to 1761, when the principal local tribes of Abu Dhabi, the Bani Yas, who were settled in an inland oasis, moved to the coastline seeking better living conditions. (Elsheshtawy, 2010). Presence of water helped and it grew as a permanent settlement devoted to fishing and pearling. A turning point in the development of Abu Dhabi came about in 1953, when Abu Dhabi Marine Areas Ltd. (ADMA) obtained offshore oil concessions resulting in royalty payments. This triggered the development process, which accelerated when Sheikh Zayed bin Sultan Al Nahyan took over as the ruler in 1966.

The task of making the masterplan of the city was undertaken. In addition to extensive greening, the main concerns of the planners were a responsive Arab Islamic style, identifying areas of development and the problem of settling the native Bedouin who were accustomed to a migratory, nomadic lifestyle (Raban, 1987). The 1960s to 80s saw a surge in construction activity. High densities were attained since land was parcelised into small chunks and allocated to nationals. The possibility of installing infrastructure and the reliance on technology for cooling buildings lifted the limits on urbanizable land and waterfront development and land reclamation gained importance. The urgency for development placed a greater focus on planning and land sub-division.

Vision 2030 and proposals for islands

In comparison with other oil-based economies of the region, Abu Dhabi may be differentiated in the restraint that it has exercised in its growth and development, primarily due to the greater availability of natural resources. This restraint has allowed it a second mover's advantage (Rogers 1983) and a chance to deliberate upon its growth directions by preparing a vision, which includes socio-environmental concerns in addition to market-driven forces. The Plan Abu Dhabi 2030: Urban Structure Framework Plan, prepared by the Urban Planning Council (UPC) in collaboration with the Abu Dhabi Council for Economic Development (ADCED) was released in 2007. The document envisages Abu Dhabi as a 'leading 21st century Arab capital, that is based on a range of factors to ensure sustainable growth and a high quality of living'. (Plan Abu Dhabi 2030). In order to achieve this vision, the planning principles follow the 4 pillars of Estidama (a sustainability program, customized for the Middle East – Environment, Economy, Society and Culture. The Plan Abu Dhabi 2030, documents the initiatives to develop the peripheral islands of Abu Dhabi to ensure they are an important part of the city's identity. It is envisaged that the city be defined as much by the natural islands and dunes surrounding it as the infrastructure, streets and homes to be developed. (Executive Summary, Plan Abu Dhabi 2030). Strong emphasis is being awarded to leisure and tourism and key projects which are earmarked towards this purpose include the Sadiyat Island as the cultural district, Yas Island with a Formula One circuit, the manmade Lulu island, which will potentially hold a major park and the Desert Islands projects. The Environmental Framework Plan proposes a Green Gradient to regulate the development of the islands by assigning a series of inhabitation levels, ranging from 'Park Core Islands' to City Edge Islands' (Plan Abu Dhabi 2030, p 51, 138). The Central Business District (CBD) that is scattered over several diverse islands is consolidated on Al Maryah Island to improve its legibility (Plan Abu Dhabi, p55). Fig1. provides an overview of the key island development project.

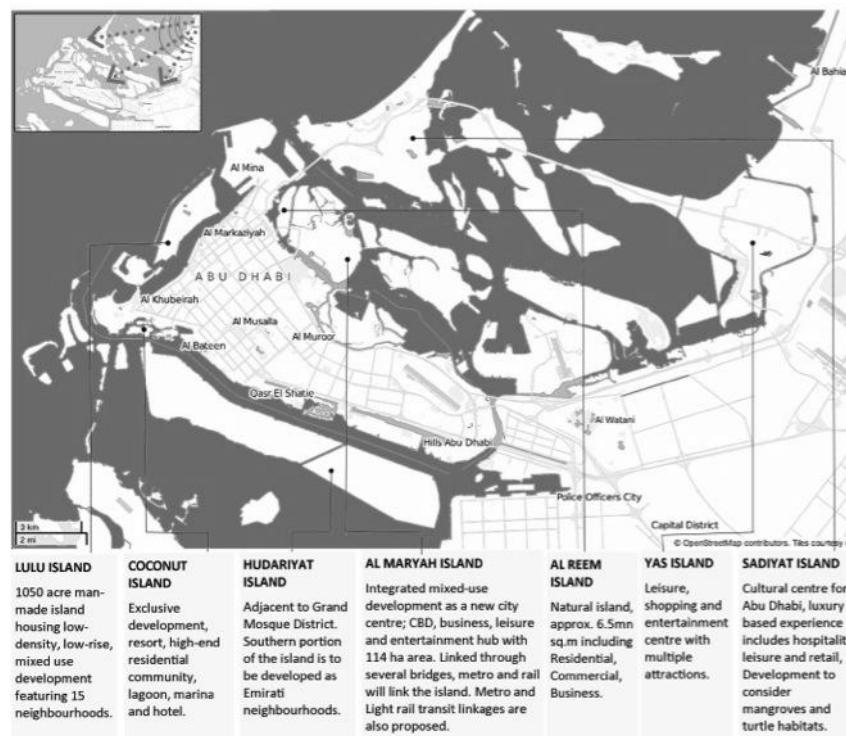

Figure 1. Map of Abu Dhabi – New island proposals and initiatives in Plan Abu Dhabi 2030. Developed on maps courtesy OpenStreetMap.org.

Developing the Islands – Place-Branding

The isolated self-contained, configuration of islands as well as the complete absence of any development presents a ‘blank slate’ to the developer. Though development is guided by an overall vision for the city as a whole, drawing references from the surrounding fabric often becomes difficult and convoluted. Castello (2010) discusses the complementary nature of place-making and place-marketing in the genesis of places and comments on the growing importance of marketing in creating associations with places. Hashim (2012) examines the efforts of the Office of the Brand Abu Dhabi as part of the city’s efforts to place itself as a globally significant city and studies the case of Sadiyat Island. The strong imageability of the water also means that celebrated architectural icons are often commissioned to generate an exciting waterfront experience (Zoe, 2012).

Leisure, recreation and entertainment are dominating functions employed in the mechanism of place-branding of the islands. Hannigan (1998), refers to places intended for leisure and entertainment, permanently offering an attractive mix of festivity and social interaction. Sassen and Roost (1999) discuss the role of entertainment industry in creating urban places dedicated to products and leisure services. Two of the most significant island projects, reflective of these trends in Abu Dhabi are the islands at Yas and Sadiyat which have seen extensive development in erstwhile empty islands. Yas island is intended to be a recreational and entertainment node while Sadiyat will be a cultural district and both developments have been positioned at a global scale.

Sadiyat Island, an island half a kilometer off the coast of Abu Dhabi is being pitched as a venue for staging classical concerts, art exhibits and a major book fair. It comprises of 4 museums, each designed by a celebrity architect and 19 pavilions, varying in size from 2000 to 10000 sq. m. strung along a water canal, which have been conceptualized in order to host an Art Biennale. The Art Biennale will be a regularly recurring art exhibition (every 2 years), which is inspired by the historically acclaimed ‘Venice Biennale’, which was first held in 1895. It is interesting to note that the masterplan while planning for events also acknowledges the fact that the events will be occurring only for a short duration. Hence the pavilions have been designed such that one face of the pavilion fronts the canal and the other face responds towards the commercial development within the island. This creation of a flexible framework appears as an important characteristic when planning for large events since it addresses their temporal nature. Other characteristics of this development trend are the creation of thematic environments and the dominance of projects delivered by star-architects and the pursuit of superlatives (Fig2).

Figure 2. Place-Branding of Sadiyat Island through signature architecture (Source: The Sadiyat Brochure).

The development of islands incurs large costs due to the extensive infrastructure requirements and landworks entailed. Hence there is often a tendency to parcelise the land and divide the island project into sub-projects in order to distribute the risks of investments. This can at times cause the public realm to become fragmented.

Recharging the Void

Initially designed as a compact city, concentrated around the Corniche and the port, the downtown area displays a strong imageability that reduces towards the periphery. Peripheral areas may be characterized by several features such as low density, large sizes of land parcels and reduced imageability and activity. Fabric dating from various development periods often surrounds them. With the development of peripheral islands, these areas figure as voids in the city fabric, since it appears as though the development has leapfrogged over them. In the modified context of the developing peripheral islands, such urban voids are gaining a renewed value due to the significance of their location at the cusp of different fabrics and are likely to undergo dramatic urban transformations in the near future (Fig3).

In the contemporary urban territory, the void or the un-built becomes the structuring elements and thus should be studied as one of the components – as important as the built one. (Cortes, 2006). It would be very useful to develop design guidelines that address the opportunistic value of such sites – the possibility of saving them as open spaces for the city, as spaces from where the fabrics dating from different periods may be observed, as spaces that serve as important connections between different districts and as spaces which allow informal activity and inclusiveness. One such area in Al Zahiya, previously known as the old Tourist Club Club Area was studied and documented by students of an Urban Design Studio at Abu Dhabi University (Fig3).

Figure 3. Above - Satellite image of the old TCA area showing urban fabrics ranging from different development periods (source: Wikimapia. Right – Graphics showing the appearance of voids in the urban fabric as peripheral islands are developed).

Connecting the Islands: Expanding the Periphery

The word ‘island’ itself is used in common language to represent an independent entity that has little or no relation with others. In urban design literature, the term islands and archipelagos have been used to refer to the extent of exclusiveness of developments (Buchanan, 2013). Adham K, (2010), uses the term island both to make references to geographical configuration as well as to allude to new forms of urban archipelagos prevalent in Doha and the region.

Abu Dhabi, an island itself, is located less than 250m from the mainland, separated by a shallow stretch of water, which gave it a strategic advantage but posed an obstruction to trade and transport (Khaleej Times). In the early 1950s, when a proper link to the mainland became essential with the oil discovery, Petroleum Development (later Abu Dhabi Petroleum Company) had a narrow causeway built over this. Under the leadership of Sheikh Zayed, a decision was taken to turn the causeway to a bridge and the Al Maqta bridge was opened in 1968 (Radan, 2014, Khaleej Times). This was followed by the Mussafah bridge and more recently, an iconic connection, the Sheikh Zayed Bridge, designed by Zaha Hadid was opened in 2010 (Construction Week online). The 3 bridges serve as portals to the city. The 3 major arterials extending from these portals were the main routes through which the city was experienced. The strong directionality of these routes, together with the linearity of the landmass, helped establish the city image, reinforcing the perception of moving to and away from the city centre.

The traditional linear / grid configuration of transportation configuration is gradually being replaced by a network configuration (Fig4). The Eastern Ring Road or Salam Street (now renamed Sheikh Zayed bin Sultan Street) was extended to the Corniche end of Abu Dhabi island where it turns to join the other arterials Khaleej al Arabi and Old Airport road). The Sheikh Khalifa Highway, E12, connects the city to the 3 major islands – Sadiyat, Jubail and Yas, re-entering the city close to the airport. Similarly the manmade island, Lulu, which is currently accessed only by ferry, is set to be connected to the mainland at the Marina breakwater and the Port Zayed. The high-speed arterial thus created would circumscribe the older parts of the city, quite like a ring road. The direct connectivity would allow one to travel straight from the airport to the island destinations, bypassing older areas of the city.

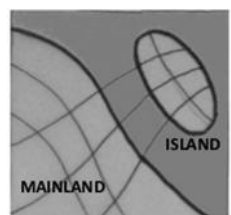

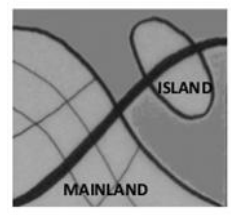

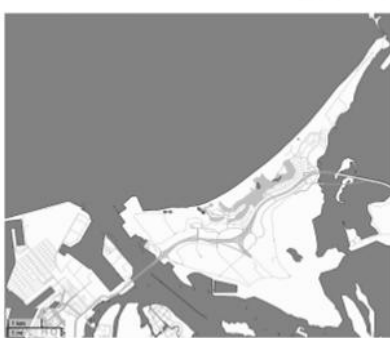

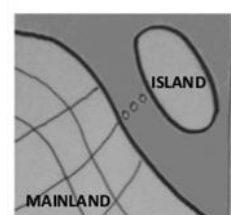

Figure 4. Above – Planned improvements in the Surface Transport MasterPlan for Abu Dhabi (source: STMP, Abu Dhabi. Right - Changes to the Transportation structure of Abu Dhabi from linear / grid type to a network configuration in relation to development of peripheral islands).

These new connections could be understood as creating a ‘string of beads’ configuration of urban centres which are carefully linked to important transport nodes thus facilitating a global connectivity. Since movement routes play an instrumental role in the perception of the city, this modified movement structure will be integral to the development of the new urban morphological form and the traditional perception of the city as a ‘T’- shaped island.

Further, based on the nature of connectivity between the city and the island, there appear to be 3 models of islands: Inclusive, Connected and Exclusive. A comparison of the 3 types has been described in Table 1.

The Al Maryah island, (Fig5) an example of an inclusive island is being proposed as the new Central Business District and will therefore support the highest concentration of office space in Abu Dhabi. Since the CBD shall incorporate adjacent edges of Al Mina, Al Reem and Abu Dhabi islands, it is planned that existing city streets will be extended into the proposed islands, through modestly scaled bridges (Abu Dhabi Surface Transport Masterplan STMP, p51).

Table 1. Types of Islands based on connectivity. Maps of islands sourced from OpenStreetMap.org.

		<p>Location of island very close to city.</p> <p>Attempts to extend city structure and fabric.</p> <p>Greater degree of access and permeability.</p> <p>Integrated development.</p>
		<p>Use of Place-branding to create new development.</p> <p>Projects tend to address a global audience eg.—Leisure destinations, cultural and entertainment attractions etc. High speed global connectivity to allow access.</p> <p>Some areas have environmental emphasis</p>
		<p>Either reserved for a gated community or having a strong environmental emphasis.</p> <p>Access through private roads and / or through ferries.</p> <p>Possibility of considering off-the-grid infrastructure to reduce environmental impacts.</p>

The Connected type of island presents further issues in terms of morphology. Such islands are characterized by a strong urban edge created due to the transport connection that often dissects the island. An example of this may be seen on the Yas Island where the Sheikh Khalifa Highway divides the island into areas, which are also being developed as Yas North and Yas South (Fig6). Though an attempt has been made to propose parks which will serve as seams and link the two sides, they have a limited effectiveness in serving as seams.

Figure 5. The Al Maryah Island, an example of a development integrated with surrounding fabric. Left and top right - Photos of exhibits in The Galleria Mall, Bottom right – View of waterfront of Al Maryah Island with the main city in the backdrop.

Figure 6. Clockwise from top left: Map of Yas Island showing the E12 highway dissecting the island into Yas north and South – Source: OpenStreetMap; View of the highway creating an urban edge; View of the Gateway Park designed as a seam for Yas North and South.

Connecting the local island-based movement networks to the city arterial also affects the urban form and image of the proposed development. Since this involves geometries and traffic interchanges, which are predominantly concerned with regulating the traffic speeds, they can interfere adversely with intuitive way-finding due to maze of interchanges and ramps and also the presence of buildings on the transport routes. This may be experienced through the example of Manarat al Sadiyat (Fig7), a visitor centre designed to convey the vision for the island to the visitors.

Figure 7. Access to Manarat al Sadiyat, Map courtesy: OpenStreetMap.org

The Abu Dhabi Surface Transport Master Plan (ADSTMP) also proposes that the planned land-based transport network will be supplemented by ferries and water taxis to serve the off-shore island districts in an effort towards creating a multi-modal transport system

Conclusions

As Abu Dhabi pursues its vision for the future, it is quite evidently doing so through massive development projects, proposed on its peripheral islands. The need to balance environmental issues, urban form and city image with the pressures of development and expansion thus comes into the forefront.

The decision to develop large areas over short periods of time on a geographical configuration which is physically isolated has led to the predominant use of place-branding as a favoured means of place-making. Place branding has simultaneously reinforced and leveraged upon the exclusiveness of the island landform. Place branding in Abu Dhabi's islands has focused on hosting mega-events and emphasizing the islands for their natural value. The Green Gradient specified in the Plan Abu Dhabi 2030 is a positive effort that codifies the role of environment in the future development of these islands. Since the hosting of mega-events and creation of architectural icons is a strategy adopted by cities to boost tourism (Richards and Wilson, 2005), it is therefore oriented towards an international audience. Hence direct connectivity through global links such as the high-speed transport arterials and access from the airport gain significance in these projects.

As peripheral islands develop as nodes of activity, a reconfiguration of land values is brought about with erstwhile fringe areas and voids in the urban fabric gaining a renewed importance. The voids hold importance since they can connect and stitch together different fabrics and allow better integration and continuity of the public realm. Development guidelines that recognize this opportunity and addresses this urban type would be useful in ensuring that these issues are appropriately dealt with.

Connections required to make the peripheral islands accessible are transforming the traditional linear / grid form of the city circulation to a network type which connects the dispersed nodes. The morphology of the island itself is influenced by the extent of connectivity with the main city, with some islands retaining their exclusiveness, some linked through arterials and others being integrated with the main city. Both the exclusive and connected models of islands have the merit of limiting the impact of the transport infrastructure on the natural systems and mangroves.

The high costs of development on islands means special attention is required to ensure that short-term economic considerations are balanced with long-term goals of vision, waterfront development and sustainable public realms. Further research and morphological studies that compare the urban form of the different types of islands, potential guidelines for fringe areas and voids and urban infill would be very useful.

Restelo neighbourhood: a paradigmatic example of urban form overlapping

Patrícia Bento d'Almeida

Instituto Universitário de Lisboa, DINÂMIA'CET-IUL, Av. das Forças Armadas 1649-026 Lisboa, Portugal. Email: pbdao@iscte.pt.

Abstract. *This paper reviews the numerous phases of the urban growth planned for the Restelo neighbourhood, located in Lisbon, which is regarded as a paradigmatic example of an amalgam of urban interventions in the same territory. Throughout the twentieth century the growth of the Portuguese capital was directly associated to political decisions made by the Municipality and the Ministry of Public Works. The intention to develop a housing neighbourhood in the south-west limit of the city emerges from a dictatorship minister that saw, in this territory, a perfect scenario for Faria da Costa to put into practice the urban knowledge acquired in Paris. But if Duarte Pacheco had been called an urban planner, the subsequent politicians called in architect teams to redraw what had not been yet built. Multiple forms expressed in this urban agglomeration testify different solutions in urban design. This paper aims to: i) reveal the evolution of the urban form in the Restelo neighbourhood; ii) contribute to the understanding of the urban form development in Portuguese Urban History; iii) provide historical basis for the debate on the respect on previous urban design solutions. Still with land to urbanize, the Restelo is a territory open to future urban proposals.*

Key Words: Restelo-Portugal, urban History, urban form, municipality.

Introduction

This paper intends to present a critical view of the several phases of urban growth performed on the Restelo neighbourhood, from the first proposal “Ajuda Hillside Urban Plan” (“Plano de Urbanização da Encosta da Ajuda”, 1938) developed by the first Portuguese architect graduated in Urbanism, to the public contest of ideas “East Zone Restelo Hillside” (“Zona Nascente da Encosta do Restelo”, 1991). Due to the fact that this information is deposited in sparse archives and is widely unknown to the scientific community, the Portuguese historiography had not yet been totally released. This served, therefore, as motivation for the development of a PhD research (d'Almeida, 2013). We live in a period where the population inhabits territories that are constantly subjected to urban and architectural interventions. Based on the experience of the Restelo neighbourhood, we hope to contribute to the debate on future interventions that will take place on this or other territories. Justified value: 1º) The comprehensive overview of Duarte Pacheco's definition of Lisbon's growth lines; 2º) The visionary attitude of this Minister of Public Works of sending to the Institut d'Urbanisme de Paris one Portuguese architect to study Urban Planning and to bring back to Portugal the knowledge acquired from Henri Prost (1874-1959), Jacques Gréber (1882-1962), Georges Sébille (1879-1962), Donat Alfred Agache (1875-1934) and Etienne De Gröer (1882-1974); 3º) The lack of vision of the politicians that followed Duarte Pacheco and consistently contributed for the changes that occurred at the Restelo neighbourhood, making this a paradigmatic example of overlapping urban form.

This paper is organised in four parts. After this introduction, the second part describes “The heavy task of Duarte Pacheco” part of the assuming the lead of the municipality of Lisbon, accumulating it with the position of Minister of Public Works as he idealizes the Lisbon city's urban growth without Portuguese urban planners. The third part demonstrates the transition “From Ajuda Hillside to Restelo Neighbourhood”, showing the passage of an agricultural field to an urbanized territory, according to the model of Garden City. The final part of this paper

focuses on the evolution “From Neighbourhood to Neighbourhoods”, exposing the overlapping of urban plans and, consequently, urban forms over more than fifty years.

The heavy task of Duarte Pacheco

In 1938, the engineer Duarte Pacheco (1900-1943) (Costa, 2012), Minister of Public Works (1932-1936 and 1938-1943), accumulated political responsibilities when he assumed the post of Mayor of Lisbon (1938-1943) – “I know it's a heavy task that is being required of me and I realize the extent of the sacrifice that the acceptance of this duty represents” (Pacheco, 1944), were the words in his inauguration speech. In the funeral ceremonies held after his death, the deputy president Eduardo Rodrigues de Carvalho recalled a walk he had with the Minister: “from that bright spirit flowed in torrents of thoughts on the Eduardo VII Park, the highway, the aesthetic arrangement of petty buildings that line the Avenue and the Restauradores Square (...) the Rossio arrangement, the downtown traffic, the vision of the tunnels starting from the Restauradores by the Corpo Santo, and from Socorro to St. Domingos, to tackle the problem of Almirante Reis’ connection with Rossio, all treated with great depth” (Carvalho, 1944). Pacheco’s passage in the political life was brief but active, creating conditions to achieve what he envisioned for the city of Lisbon: the “Capital of the Portuguese Empire” (Lobo, 1995). Firstly, to avoid the constant hiring of foreign professionals and due to the lack of Portuguese urban planners (Ferreira, 1987), he opened a contest for a Portuguese architect to specialize in Urbanism in the Institut d’Urbanisme de Paris; secondly, he hired the newly graduated architect in urban planning to integrate the technical team of the Municipality of Lisbon shortly after his return to Portugal; finally, he requested this urban planner to develop much of his idealized urban production for the city of Lisbon. João Guilherme Faria da Costa (1906-1971), the first Portuguese urban planner, in a first stage and among other projects was commissioned to give urban form to Ajuda Hillside (1938), Areeiro (1938), Alvalade (1945-1948) (Costa, 2002) and link 24th July Avenue to Comércio Square (1947).

From Ajuda Hillside to Restelo Neighbourhood

In 1938, the 300 hectares of the “Ajuda Hillside”, located on the western limit of the municipality of Lisbon, were the focus of the first urban interventions part of the “Ajuda Hillside Urban Plan”. With some urgency, this plan aimed to transform a territory occupied by farms and palaces into a large residential neighbourhood, to accommodate 36.000 inhabitants with generous financial resources. Positioned in the back slope of the Jeronimos Monastery it should also served as a scenario for the Portuguese World Exhibition (1940) and as the beginning of the Estoril Coast, which had suffered some changes part of the urban development plan carried out by Alfred Agache in 1933.

With the axis defined by the Belém Tower and the St. Jerónimo Chapel, as Beaux-Arts style, the urban planner Faria da Costa designed the plan with three main motorways lined with vegetation – Dom Vasco da Gama Avenue/Descobertas Avenue, Torre de Belém Avenue and Jerónimos Street/Ilha da Madeira Avenue – taking advantage of the urban scenario and strategically enjoying panoramic views over the Tagus River. A third Avenue, designated Restelo Avenue, follows the contours and guides the urban network with concentric streets that look over the river like an amphitheatre. This Avenue outlined the areas to urbanize in the 1st and 2nd phase of urbanization. As in the new Australian capital (1911) projected by Walter Burley Griffin (1876-1937), for Restelo Faria da Costa thought about a residential neighbourhood to be seen from Belém. The buildings of greater height were placed in the higher elevation of the slope and the single-family homes were placed in isolation in the plot along the “galleries” that make up the “audience”. Looking for a certain classical monumentality as Henri Prost did in Casablanca (1915-1922), a church completed the urban ensemble. Following the

Ebenazar Howard (1850-1928) model of the Garden City (1898), matching the city and the countryside, Faria da Costa wanted to create a self-sufficient neighbourhood whose boundaries were defined by a peripheral green belt – the Monsanto Park – where the discomfort of dwelling in the metropolitan area is diluted with the contemplation of landscaped squares that remind us of Letchworth (1902-1906), designed by Raymond Unwin (1863-1940) and Barry Parker (1867-1947). Applying the zoning principle Faria da Costa created residential areas separated from commercial areas and opened spaces. The contemplation of the commercial centres concentrated near the dwellings creates neighbourhood units that serve the resident population and ensure a certain morphological and social homogeneity.

From Neighbourhood to Neighbourhoods

The Restelo neighbourhood was already under construction when it gave the first major change of the original “Ajuda Hillside Urban Plan”. With Duarte Pacheco’s death (1943) the new Minister of Public Works (1947-1954), José Frederico Ulrich (1905-1982), leads the urbanization works differently, taking Restelo neighbourhood to very different directions comparing to what was conceived by the earlier Statesman. Called again to design at Restelo, Faria da Costa is at that time requested to change the general urban plan with the “Study of Economic Houses of Ajuda Hillside Neighbourhood” (“Estudo do Projeto do Aglomerado de Casas Económicas da Encosta da Ajuda”, 1947-1952), giving rise to the construction of the identified Restelo Economic Neighbourhood. As advocated by the architect Raul Lino (1879-1974) (Pereira 2013) this economic neighbourhood was composed of single-family houses, for state employees, military and their families. Consisting of approximately 460 attached houses, the presented solution is distinguished from the initially private homes because the economic houses were distributed in line, forming autonomous blocks built with each type of house oriented in the same direction, seeking to provide equal living conditions. As a consequence, streets with continuous buildings in block arise, approaching the urban form designed by German Modern architects, namely by Walter Gropius (1883-1969) author of Dammerstock neighbourhood (1928-1929) in Karlsruhe, Germany. Although Portuguese laws considered, at that time, four classes of houses (Class A, B, C or D; Type I, II or III), the Restelo Economic Neighbourhood only contemplated the upper classes C and D, because they had to be integrated with the houses previously built and whose lands had been acquired in public auction by those who offered greater value.

The restructuring of “Ajuda Hillside Urban Plan”, considered of great importance to promote a significant urban and social change, was readily exposed at the exhibition 15 Years of Public Works: 1932-1947 (1948), held at Instituto Superior Técnico (Lisbon Technical University) under the support of the Government in an initiative by José Frederico Ulrich. About one year after the inauguration of this economic neighbourhood, with Álvaro Salvação Barreto (1890-1975) at the presidency of the Lisbon Municipality (1944-1959), Faria da Costa was invited to re-urbanize the land north of Restelo Avenue with the urban plan of the “Residential District of Ajuda Hillside – 2nd part” (“Bairro Residencial da Encosta da Ajuda - 2ª Fase”, 1953). At that moment that urban planner was looking to partially break the central avenue with the creation of a promontory around the St. Jerónimo Chapel. A perpendicular axis to the main avenue defined the northern limit of the intervention with blocks of four floored buildings located perpendicularly to the street axis. This review of the previous general urban plan was never implemented. The planned roads that snaked the steepness of the slope accompanying it with the constant presence of single-family houses, as we shall see, will be partially replaced by renewed urban interventions that gave priority to modern hierarchical streets where multifamily houses prevail.

The creation of the Office of Municipal Urbanization Studies (Gabinete de Estudos de Urbanização, GEU 1954) allocate 100 hectares of land in Restelo for the development of the “Restelo Hillside Urban Plan” (“Plano de Urbanização da Encosta do Restelo”, approximately

1954). The GEU team planned tower buildings and lined buildings to respond to the increasing of the population. Now were the reflections of CIAM congress, namely the Charter of Athens (1933-1941) that fascinated the young architects and urban planners. Concentrating height housing blocks independent from traffic routes, each outlined "housing unit" was relieved with the presence of green spaces, as idealized in the British New Towns planned in Harlow (Frederick Gibberd, 1947) and Roehampton (London County Council, coordinated by John Leslie Martin, 1952-1959). In each cell, the equipment considered essential for the neighbourhood consolidation were: church or cultural centre, commercial centre, schools and administrative institutions. A prioritisation of the traffic routes led to the disappearance of the "traditional street" for main motorways where blocks or buildings were built in line and located obliquely to get better solar exposure. The "Lisbon old blocks" disappear and the "Modern City" appears. However, to respond to the requests for housing cooperatives who wanted to built homes for its members, Pedro Falcão e Cunha (b. 1922) and José Aleixo de França Sommer Ribeiro (1924-2006), architects that worked for the GEU, were instructed to develop the "Readjustment of the 2nd Phase of Restelo Hillside" ("Reajustamento da 2ª Fase da Encosta do Restelo", 1959). This urban plan replaced, once again, two blocks per single-family houses and attached houses, solution predicted in 1953 by Faria da Costa. At this planning stage, three categories of buildings were predicted (Category I, II or III), for three different salaries (200\$00-300\$00, 400\$00-600\$00 or 700\$00-900\$00). Next to Ilha da Madeira Avenue, six tower buildings with an "H" plan and 96 apartments were contemplated (category II), which should make the transition between the cooperative housing and housing for category III. In a sense, this phase of urbanization has been forgotten by the Portuguese historiography, perhaps because it was not entirely built. However, it is important to remember that this plan was developed by the same architects that worked at the urban plan of Olivais Norte (1955-1958), a very similar proposal developed after "Restelo Hillside Urban Plan".

During the 40s of XX century the Ajuda Hillside was faithful to tradition. During the 1950s over 400 projects of scarce equipments and numerous houses were approved for the entire Restelo neighbourhood. Among other Portuguese traditional single-family dwellings or where the history of architecture from the fifteenth and sixteenth centuries were somehow represented (Acciaiuoli, 1991), there were the finest examples of Modern Architecture built in Lisbon. During the twenty years that followed, diplomats, artists and intellectuals hired the most renowned architects to project their private houses, making this place a strategic point to test the modernity. Although the division of the plots do not meet the requirements of the requested programs, this was no impediment for the simultaneous acquisition of two plots. Serving as a project-lab to the youngest class of architects, these projects were exposed at the General Exhibition of Fine Arts (1946-1956), the greatest "publicity event" where several generations of architects and artists exhibit their work, in opposition to the exhibitions organized by the regime.

With França Borges at the presidency of the Lisbon Municipality (1959-1970) other architects employed by the City Hall were called to intervene with partial urban plans replacing the previously prepared by GEU. In 1965, Ruy António da Silveira Borges (1916-1978) was responsible for the "Study of urban arrangement and architectural complex of the land next to the C.G. Street" ("Estudo do conjunto arquitetónico e arranjo urbanístico do pormenor do terreno junto à Rua C.G.", now Ilha da Madeira Avenue) whose five modern housing blocks were built by the same project; a year later Manuel Alves de Sousa (b. 1925) was invited to prepare a detailed plan of a housing development located at the southern edge of Cell C, which matches what was planned. After the building construction of the Ministry for Colonial Affairs (1960-1962), the remaining area was being occupied by buildings on a large number promoted by civil construction companies or groups of people associated to premeditated investment.

The lack of technical expertise at the municipal services leads to other professionals. Between 1964 and 1970 the architect Francisco Zinho Antunes (1921-2002) and the engineer Eurico Ferreira Gonçalves (1916-2005) developed the "Study of Restelo and Caramão da Ajuda Urbanization" ("Estudo de Urbanização do Restelo e Caramão da Ajuda"), commonly known as

"Hight Restelo Plan" ("Plano do Alto do Restelo"). This urban plan had several phases due to the guidelines given by the urban planner George Meyer-Heine (1905-1984) that was responsible for the revision of the Lisbon Master Plan. At this time this urban plan was limited to 30 hectares of surface circumscribed in an adjacent neighbourhood area, bordering the Monsanto Park and the Caramão da Ajuda Economic Neighbourhood, designed by the architect Luís Benavente between 1947 and 1957. This new team planned and constructed tower-buildings from 8 to 12 floors interconnected by buildings from 1 to 3 floors. Following one of the central concerns of the Team X (1953-1984) – constituted by Alison Smithson (1928-1993), Peter Smithson (1923-2003), Jaap Bakema (1914-1981), Georges Candilis (1913-1995), Aldo Van Eyck (1918-1999), Giancarlo di Carlo (1919-2005) and Shadrach Woods (1923-1973) – these galleries placed at different levels intended separate the pedestrians from the vehicles and favour human relationships between the communities that faced the commercial spaces. All these tower-buildings functioned as a barrier, forcing Caramão da Ajuda residents to contour the buildings than to cross through the galleries as previously predicted. There is a certain constraint between the coexistence of different social classes.

The new Chair of the Council led by Santos e Castro (1970-1972) interrupted the operation and suspended the announced 2nd phase of urbanization. This second phase should have continued the construction of the tower-buildings in the south land of Gregório Lopes Street (the cornice line), where a Centrum on a platform was also planned. It was too late to "remedy" the northern slope view of the Jeronimos Monastery but it was necessary to avoid the negative effect of the scale emphasized by the building towers in an elevated area of the city. This construction forever altered the view of Lisbon from the Tagus River. The architects Nuno Teotónio Pereira (b. 1922), Nuno Portas (b. 1934) and João Paciência (b. 1947) and the landscape architect Gonçalo Ribeiro Telles (b. 1922) formed a new team to design the next urban changes at Restelo neighbourhood. These professionals had the obligation to keep the already existing population density but significantly reduce the height of the prospected buildings. Thus, before the recent Lisbon General Urban Plan (1977) defined the guidelines for the "Restelo Zoning Plan" ("Plano de Pormenor do Restelo", 1971), the urban plan is going to turn the tower-buildings horizontal and create low height blocks, recovering the concept of elongated blocks and traditional streets that point to the Tagus River. This plan was looking to dilute the nearest neighbourhood plans partly built; creating a passage between the south housing area (Faria da Costa), to the east block-units (GEU; Silveira Borges; Alves de Sousa) and the north tower-buildings (Zinho Antunes and Ferreira Gonçalves).

Meanwhile, the Public Urbanization Company of Lisbon (Empresa Pública de Urbanização de Lisboa, EPUL) was created (1971-2002), giving them administrative and financial autonomy. This company had a prominent role in the field of urban planning and housing in the city of Lisbon. Some of the municipal planning processes were transferred to this company, including the "Restelo Zoning Plan" whose urban arrangement had been previously approved by the City Council and the housing projects created by the same team of designers, to which joined the architect Pedro Viana Botelho (b. 1948) and the landscape architect Francisco Caldeira Cabral (1908-1992). EPUL continued the process with the opening of a tender for the construction of the "pilot-block", located on the south end of the enterprise, called the "EP Zone" (Zona EP - Estudo Prévio). This district included town houses which aggregated a set of courtyards and terraces and a collective block-unit that took advantage of hits on gallery. With a new Mayor (1972-1974), the Lieutenant Colonel Jorge da Silva Sebastião (b. 1919), EPUL planned a phased construction but did not build the central area that included a civic and cultural centre, a hotel, offices and a church.

The transition from a dictatorship to a democracy had further repercussions on the entire process. Under claim of the EPUL services, this public company decided that the new projects should be developing internally. The building projects located on the western side were given to the architect Vítor Alberto (b. 1938), employee of this public company. At odds with the "Restelo Zoning Plan", this architect increased two floors to the building projects. Curiously, these projects were awarded with an Honourable Mention of the Valmor Prize (1988), the most

important recognition given in Portugal to an architect and his work. Although the new chairman led by Nuno Krus Abecassis (1929-1999) had led all building projects located on the east slope to the authors of the zoning plan, only the called “Pink Block” was built (“Quarteirão Rosa” 1984-1987, honorable mentions of Valmor and Municipal Award in 1987 and 1988) because in 1984 EPUL decided to review the projects and the allotment of five hectares located at the nascent part, which were still available for urbanization. Already under the tutelage of the director Joel Hasse Ferreira (b. 1944), in 1991 EPUL opens a contest of ideas for the “East Zone Restelo Hillside” (“Zona Nascente da Encosta do Restelo”) which qualified the project submitted by the architect Nuno Leónidas (b. 1954) (see figure 1).

Conclusions

From the selected proposal in contest, the “Slope of the Monastery” (“Encosta do Mosteiro”) was built. Because the basic characteristics of the “Restelo Zoning Plan” were not ensured, the

architect Nuno Teotónio Pereira criticized the urban intervention on an article to be published in the 35th EPUL anniversary (Pereira, 2006). Presently, still to urbanise, are some plots called “High Restelo” (“Alto do Restelo”) and “Embassies Plot” (“Terreno das Embaixadas”). This means that the passage of a dozen presidents by the Municipality of Lisbon was not yet sufficient to terminate the development of this urban agglomeration. It is with difficulty that we recognise this part of the city as a neighbourhood because the equipments that should give to this place some autonomy were not built. We have seen that since the late '30s until now the change of leadership also meant the changing of the "urban-planner" responsible for the Restelo planning. To define areas of the capital expansion the engineer Duarte Pacheco appealed to an urban-planner and a single urban plan was developed to create a distinct elite residential area. The leaders that succeeded in the Municipality and in the Ministry of Public Works requested the collaboration of other professionals to respond to the needs of the moment. Each professional did not take into account the previously developed plans, but saw them as a condition. Each architect will give effect to a particular urban form in his design area. Thus, by way of example in the city of Lisbon, the urban agglomeration of Restelo is the result of an overlap of urban forms (see table 1).

Acknowledgments

The present work benefited from the input of Margarida Acciaiuoli and Michel Toussaint Alves Pereira, who were the supervisors of the PhD thesis research that conducted to this paper (d'Almeida, 2013).

Abstract. *The origin of Évora dates back a few millennia, and this fact caused successive urban forms that were diachronically adapting to the needs of a very diverse sum of generations. The walled city lies consolidated since the late fifteenth century, and integrated in the 40s of last century the first Urban Plan of the city written by Étienne de Gröer. This plan and the sequential integrated a spatial structure based on urban axes dating back to the Roman Cardus and Decumanus in the Roman times. These urban axes determined by redrafting the insertion of new pro-active roles in the case of pre-existing axes. The formation of new urban fabric took place with the creation of new axes, obtained at the cost of drastic demolitions in the dense and consolidated hull. New urban centres were created extramural opposing the proposal made by de Groër who advocated the establishment of a city walled garden surrounding the nucleus.*

Key Words: Urban plan, urban development, axes.

Introduction

Étienne de Gröer ⁷¹ preliminary urbanization plan of the city of Évora

The preliminary urbanization plan, designed by the architect – urban planner Étienne de Gröer prepared to Évora, which had its beginnings in 1942, was approved by the Town Hall in 1945 and sanctioned by the government two years later. There de Gröer proposed different types of interventions for different urban scenarios:

Walled city area – is an area consisting of buildings of various kinds, and that over the centuries has undergone a process of gradual consolidation. The author advocated the natural continuation of its densification, the reformulation of some not very dense urban fabric as well

⁷¹ Étienne de Gröer was born in Warsaw in 1882. He obtained his degree in Architecture from the Imperial Academy of Fine Arts in St. Petersburg. About 1920 he moved to France where he collaborated on numerous development urbanization plans and in various cities. In 1936 he was naturalized French and joined the Institute of Urbanism of Paris, where as a lecturer was responsible for the subject area where it was taught the principles of the garden city. Later, in the 1930s and 1940s, he, with the architects Donat-Alfred Crouch and Luigi Dodi, was invited by Duarte Pacheco to make development urbanization plans in various cities in Portugal, introducing the new urban principles that then were in force in Europe, of which we can underline the concept of the garden city that had been set by Howard Ebenezer. He became one of the main planners of the new State, being in charge of the preparation of preliminary plans or land development plans of various cities that stand out among other: Abrantes, Setúbal, Beja, Braga, Coimbra, Évora, Luanda, Sintra and Costa do Sol, with the guiding principles that governed, aiming to preserve the historic center and consider the expansion of cities, simultaneously reserving areas for essential economic activities.

as the opening of some streets which would take the appropriate requirements of the new era introducing transverse profiles, enabling a road traffic that he anticipated as rather heavy⁷².

The constitution of such axes of movement, inside the walled city space, would allowed the constructive reinforcement along their paths, according to the author, and create a more intense and adequate urban image to the demands of the new times.

The fact that such pathways strategically crossing the urban fabric, through its main centres of city life and simultaneously connecting with existing doors in the surrounding wall allowed the union between interior and exterior as well as easier access by the people that would live there and of course also a greater enjoyment by living of all the urban space .

At the inner urban space of the walled city the typology for built solutions focused essentially in continuous urban facades. Those buildings were broadened mostly by the scrapping of old hull built. Such proposals for interventions were focused on private property intended to be implemented individually by their respective owners.

In the interstitial spaces between the walled area and the new urban area surrounding the walls were provided by equipment areas, in key points, for use by residents in both areas. Such equipment was essentially schools and markets. These would have to ensure not only pedestrian access for the resident populations in its area of influence but also effective response to the distant residential areas: to this end, these spaces must always be located along the structural axis, close to the main gates of the ancient city and they should be located or from inside or immediately in the surrounding area and should also having parking areas next to them.

The new urban perimeter surrounding the city walls

Outside the entire walled urban space, that at that time was still very little occupied, de Groër proposed the construction of a new urban area⁷³ with characteristics of “garden city” surrounding the limited ancient core of the metropolis to the existing date by creating a kind of a “lung” (Brito, V., Ferreira, CT 2007) that would allow a better environmental quality⁷⁴.

⁷² The proposal to open an internal circular to Praça do Giraldo that encircling the south, the road traffic diverted allowing greater enjoyment of the space by pedestrians. This proposal, however, planned the demolition of large urban continuous long established and notorious asset value whereas its densification occurred until the fifteenth century. As for the space formerly occupied by the old monastery of Sta. Catarina, now demolished, it would be aimed at building a central hub of public transport.

⁷³ The preliminary plan of Étienne de Groër had in its genesis a new technique of urban planning based on demographic projections and integrating economic analysis. It also included zoning (advocated by Le Corbusier and the set of technicians who had been in the genesis of the Charter of Athens – reflecting his knowledge of what was happening in Europe both in the urban and architectural level) and new forms and urban programs. The preliminary plan is still held by the CME, and is composed by four plants referring to: “Plan de zones schema des grandes voies” dated 1942; “Anteplano (preliminary plan)” dated 1945; two undated drawings: one referred to as “zone plan” and the latter as “Plant of presentation.” Charter of Athens, Athens Charter about Modern Urbanism – Athens 1933 this IV International Congress of Modern Architecture, resulted in a letter which was defined as the criteria of modern urbanism.

⁷⁴ To be noted that for the city of Lisbon: “From Groër defends containment of urban development through the establishment of a green belt, called rural protection area, with an average width of 3 km. The main objective of the green belt would be to provide the city with a permanent reserve of fresh air, and in second place, isolated from the surrounding urban formations and prevent melting with these” Brito, Vasco; Camarinhas, Catarina Teles Ferreira, “Elementos para o estudo do plano de urbanização da cidade de Lisboa (1938), Cadernos do Arquivo Municipal, Direcção Municipal de Cultura/Departamento de Bibliotecas e Arquivos/Arquivo Municipal de Lisboa, n.º 9, 2007, pp. 182-183; see also Simplício, Maria Domingas V. M., *Evolução da Estrutura Urbana de Évora: o Século XX e a transição para o Século XXI*, where on p. 4 it reads: “The growth of extramural urban area was, however, very slow until 1940. A map dated 1930 points just beyond the presence of the aforementioned wards, all of them very small in size and located near the intramural city, small parts of the wards of Chafariz d' El Rei and Almeirim and the principle of the Poço Entre as Vinhas (now Bairro da Sª da Saúde)”.

In planned urban space, the building typology proposed consisted of detached, semi-detached or isolated dwellings, where free private land contributed to the creation of a continuous green environment for the entire rural surrounding area (Simplicio, M. D. V. M., 2009). According to the areas of each of the respective batches were allowed constructions and those contributed to the distribution of socio economic hierarchy of the future population that would reside in the area. Some wards have social housing such as the Bairro da Câmara where the buildings are located in twinned lots although had building areas and compartments of diminutive dimensions ensuring reduced costs.

Some of the lots in the new area to urbanize consisted at that time by rural land for which de Groër advocated different urban typologies that actually were informally constituted. Such plots were subdivided into parcels described as “avos” usually “sold” at low cost, or even donated, by the owners of the estates to rural workers of its land thus creating subtle ties of dependence because those “plots” were still legally belonging to their rightful owners despite sometimes these workers have been building their houses on those lands. We may refer as examples of these wards Almeirim (east of the metropolis), Bacêlo, Coronheira, Granito (located north of the city), and Casinha (located in the west of the city). These cadastral underlying situations were not considerate when de Groër plan was developed and approved (Carvalho, J., 1990).

Present

Having this as a groundwork plan, and after successive urbanization plans that introduced updates resulting from new requirements we came into this reality as one can see is substantially different from that recommended by de Groër proposal in the 40s of XX century.

Walled city area – for the space in question, de Groër opted for the maintenance of the medieval urban fabric without significant interventions (one of the principles advocated by de Groër in urbanization plans in which he participated) that nothing could jeopardize the unity of urban space. The rehabilitation of the buildings was aspirated, though not a fully realized goal. The private property being in possession of more than one owner, due to successive inheritances, substantially delayed this aspiration yielding properties and punctually kept them up slightly degraded. The level of outstanding public spaces interventions were being carried out in the most emblematic squares of the metropolis. In the buried infrastructure existed special care in replacing it considering its age and current requirements in particular with regard to the water, sewer, gas and optic fiber.

In more recent times the decrease of economic power or the population either of the Town Hall or the housing cooperatives, contributed to the decrease of urban interventions of social nature. Alternatively housing cooperatives triggered more targeted interventions to classes of larger economic power by tampering with the original spirit of intervention programs and being example the allotment of CTT (Correios de Portugal) situated in the walled interior.

The installation of hotel properties located within the historic center, or in large spaces still vacant as was the case for example of the Hotel Mar de Ar Wall built in the old Quinta da Palmeira, or even reusing old buildings such as the Hotel Mar de Ar aqueduct installed in the Palácio dos Sepúlvedas that was adopted for the new requirements resulting of the observed from the growing tourist demand.

New urban perimeter surrounding the city walls – Urban space delimited by increasing and actualization of urbanization plans was structured by building a set of streets, some of radial nature, other circulars that allow the interconnection of various districts scattered throughout the area surrounding the historic centre. It should be noted that part of this road structure has not been fully realized for various reasons.

Regarding to the housing typology, mainly directed to the lower classes, there were promoted by the state, social housing developments built vertically countering all the original spirit of the 40s. That was the case of the development of the Cruz da Picada (located to the west of the city) the largest urban complex built vertically for social rental which projective

features had not appropriate social and cultural characteristics for the population that would inhabit it. Concerning private projects there were implemented with some brands of typologies features of single-family, semi-detached dwellings or individual, as the wards of Tapada and Vista Alegre, and dated to the mid-twentieth century being located to the west of the city (Carvalho, J., 1990).

However, all the vast space surrounding the city walls was increasingly taken over by new illegal wards that after April 1974 were successively converted and legalized through municipal lots or detailed plans (Carvalho, J., 1990).

Later, in the 80s of the twentieth century, the Tapada and Vista Alegre as they were already sold out at the level of building plots, there were provided the triggering of a new process of subdivision with identical and temporally characteristics adapted to new generations yielding characteristics the allotment of Vila Lusitano situated to the west of the city.

It was however at the level of C.M.E. (Town Hall of Évora) and of the housing cooperatives that much of the surrounding area was built through the creation of lots intended for housing at controlled costs that, in some individual cases, came to take on the characteristics of evolutionary housing, as exemplified by the case of Malagueira (to the west of the city), some lots in Granito Centro and Bacêlo (both to the north of the city). Among the various operations of the allotments with controlled costs⁷⁵ as we can mention the example of Malagueira, António Sérgio, Casinha and Alto dos Cucos (all to the west of the city) and Granite Centre among others (Carvalho, J., 1990). These are some examples that ensured a cohesive and quality architecture and urbanism greatly due to the conditions that such types of programs demanded from their promoters.⁷⁶

After nearly seven decades passed between the proposed by de Groër's preliminary plan, and through the development and implementation of various development schemes and detailed plans that sought to resolve the problem posed by the existence of many illegal housing units genesis dispersed and separated the walled core.

With current legalization, infrastructures and densification has been a challenge only in part outdated. Its relationship with the historic centre by the solution of building urban axes was increased by its integration as it would be an effective and inexpensive method of obtaining continuous urban image over long distances.

Similar increase of the urban area through private initiatives significantly widened, though accomplished through a whole set of new illegal buildings consisting of “lots” of large dimensions – the so-called “small farms” – coming again hamper the treatment of space, making the hybrid relationship between urban and rural. It will be an overview that new decades and new generations will have to equate making the reality of today in utopia of tomorrow.

With regard to collective facilities scheduled on the edge of the urban area they were located according to the growth of housing units in development, emphasizing schools, on their various levels of education, parish councils, sports amenities and cultural facilities among others, day-care centres and the construction of a new cemetery thereby responding to the substantial increase in estimated population.

⁷⁵ The quality of construction remained that finishes being made with less expensive materials allow smaller final costs. We must mention the existence of financing contracts by the INH (Instituto Nacional de Habitação) and where the municipality also actively participated with the transfer of land at low cost in exchange for getting some infrastructures to be allocated to the poorest households, for social renting, or even self-lots in the case of individual batches.

⁷⁶ It was required that the project should be prepared by architects, with special attention to integration in the urban fabric.

Conclusions

Overall, from what was proposed in the de Groër's preliminary plan, some of the recommended solutions have been implemented, such as plots of residential areas being the example of Bairro da Câmara, and Bairro da Tapada.

Regarding the proposed road system, many of the main roads have suffered notable adjustments in terms of location and route. The cross sections also suffered adjustments resulting from the new urban concepts.

The proposed architectural typologies, with detached single family dwelling remained in some cases. With the introduction of new social concerns due to the Revolução de Abril, pilot experiences were introduced, such as the case of the Bairro da Malagueira, where it was achieved a high constructive density with single-family residential lots. Another way of trying to address the problem of housing shortage was completed in the Bairro da Cruz da Picada, state initiative to social renting, using a project type of housing in height, which was implemented in cities across the country.

As for equipment, the proposal for a central trucking zone adjacent to the Praça do Giraldo was relocated in Rua da República, inside the Old town, and was later built on the municipal lands adjacent to the Cemitério dos Remédios.

The construction of a Municipal Market proposed for the Portas de Alconchel, was relocated with a much wider dimension as a supply market of the entire region, close to Bairro de S. José da Ponte.

The utopia proposed by de Groër's preliminary plan was completed in a substantially differential way due to the natural socio-economic development of a society that has undergone significant structural changes due to very profound political changes that have altered the existing paradigm.

The new political paradigm allowed new urban experiences, some of which exemplary, as the case of Bairro da Malagueira.

Campo Alegre: the evolution and persistence of a territorial intent

Sílvia Ramos

Universidade do Porto. E-mail: silviactramos@gmail.com.

Abstract. *The decision to construct the Arrábida Bridge, induced the need to rethink the area of Campo Alegre (Porto) which led to the conceiving of the “Urbanization Plan of Campo Alegre – Future Entrance to the City by the Arrábida Bridge”, rendered by Januário Godinho. Campo Alegre had been, until that time, characterized as a set of private gardens that structured a Romantic landscape. The conceived Plan renders its transformation proposing a new collective open space linked with those existing to form a co-ordinated public park related to the new road system and the new proposed building ensembles. With this design Januário Godinho interprets Campo Alegre’s essence through understanding the environmental character of the place in a contemporary way.*

Key Words: place, garden; park, Porto, Januário Godinho

Premise

The object of this paper is the “*Urbanization Plan of Campo Alegre* [Merry Field] – *Future Entrance to the City by the Arrábida Bridge*”, commissioned by the Municipality of Porto and designed by the architect Januário Godinho (1910-1990), between 1951 and 1955.

In the wide range of different studies about Porto or the professional practice of Januário Godinho there are few that investigate specifically this Plan. Until today, the only identified pertinent reference is “*Campo Alegre: from the New City to the University*” (Guedes, 1995).

This magazine article focuses on the Plan mainly through “*Reports and Management Accounts*” of the Municipality of Porto (1954, 1956-59). It summarizes, without deeper study, some implementation issues associated to the Plan: the State and Municipality responsibilities; the affected University properties; the land expropriation process and the University facilities proposal for the area.

The article also addresses the Plan as a transforming action of Campo Alegre’s form and through this point of view, we might interpret the following: i) the exclusive responsibility of the local planning authority for the proposal, enframated by the City Plan: “*Plano Regulador da Cidade do Porto*”, developed by the engineer Antão de Almeida Garrett and approved in 1952; ii) the resolution of the entrance of Porto by Arrábida Bridge and its surrounding urban areas as the Plan’s main objective; iii) the change in land ownership, from private to public domain as the main design premise; iv) the consequences of the partial implementation of the Plan, execution of the first phase only, which corresponds currently to the major road system (Figures 1 and 2).

Therefore, recognizing the significance of this Plan in the current definition of Campo Alegre’s urban form, this paper aims to deepen its understanding. The interpretation presented is concerned essentially with the relationship between the Plan and the territory to which it was conceived. We propose to demonstrate that, despite the Plan’s intent to radically alter Campo Alegre, in its transformation, some of the the main features of the place still persist, even though its form may change.

Urbanization Plan

Since the intent of a new crossing over Douro River and the consequent setting of the Arrábida Bridge was officially proposed (1945), the design of the new road network and the urbanization of Campo Alegre, became a major issue for the Municipality.

These studies were the responsibility of the local planning authority. However, the non-exclusive dedication of the municipal services to this plan compromised a comprehensive and global solution (*Contrato*, 1951), worthy of approval.

In 1949, with the completion of the urban plans for the territory on the south end of the Bridge (Vila Nova de Gaia), the conclusion of the studies for Campo Alegre became most urgent.

The minister of Public Works and Communications, Frederico Ulrich (1947-54) had suggested hiring an architect from outside the local planning authority to conclude the studies for Campo Alegre. On one of his visits to Porto, with the purpose to analyze the activity of the local planning authority, the Minister recommends Faria da Costa (Távora, 1949) who was, at that moment, the most qualified architect from local planning authority of Lisbon (Lôbo, 1995).

Subsequently to the suggestion of the Minister and the positive assessment for the construction of Arrábida Bridge, from the Superior Council for Public Works and Communications, in 1950/51 (Cruz, 2001), the Municipality of Porto invites Januário Godinho, one of Porto's architects also recognized by its urban practice, to develop the Urbanization Plan for Campo Alegre (*Contrato*, 1951).

The invitation was addressed to Januário Godinho in 1949/50; with the main terms of the contract presented in 1951 and the work beginning in 1952.

When Januário Godinho started Campo Alegre's Plan, he was 42 years old, had completed 2 decades ago the Course of Architecture at the School of Fine Arts of Porto; and for nine years had developed plans for the urbanization of cities in the north of Portugal. His name was on the list of architects qualified to work in urban planning by the National Buildings and Monuments Committee, although he had no specific studies in town planning (Lôbo, 1995).

The State considered Januário Godinho an expert in solving problems such as the ones in Campo Alegre – 'the government had great consideration for the way he had solved the urban planning tasks he had been entrusted with' (*Contrato*, 1951).

According to the contract for the Urbanization Plan, Januário Godinho would submit to the Municipality of Porto, first a Preliminary Project and then the Definitive Plan.

The first was intended to provide advance knowledge about the way the theme was to be interpreted, to outline the adopted design and the guidelines for the Definitive Plan. The second was intended to develop, describe and regulate, with detail and accuracy, the approved Preliminary Project so that there would be no doubt when its implementation would occur (*Contrato*, 1951).

Januário Godinho presents the Preliminary Project for Campo Alegre on August 1954 (Figure 3). The study was approved by the local planning authority, the National Road Authority and the Minister for Planning and Territorial Administration (*Parecer*, 1954; *Informação*, 1954). In its report, the National Road Authority takes the responsibility for the construction of the road that, through the Arrábida Bridge, would connect Porto with the coastal cities north and south, thus, becoming part of the national motorway network (*Informação*, 1954).

With the approval of the Preliminary Project by the committees, on July 1955, Januário Godinho presented the Definitive Plan (Figure 4) and its economic study (Guedes, 1995). During the presentation he defined the intent of his proposal as a "piece of architecture" (Távora, 1995) for Campo Alegre which would be approved by the local and national authorities.

In the following years, Januário Godinho would issue technical reports on solicited changes to the Plan, presented by the responsible authorities (*Parecer*, 1957; *Informação*, no date) and would study its reformulation in order to integrate a set of University amenities (*Programa*, 1957).

In 1956, the construction of the Arrábida Bridge triggers the expropriation procedure of private terrains for the implementation of the first phase of the Plan – the major road network (Guedes, 1995).

The procedure was prolonged and complex (Guedes, 1995), in a way that calls into question the fulfillment of the other planned phases. Consequently the implementation of the Plan was never completed.

The execution of the Plan's first phase did not solve the pressing urban issues present in Campo Alegre. Therefore, they remained an important topic of Porto's future planning. Years later, the "Plano Director da Cidade do Porto", coordinated by the architect-urbanist Robert Auzelle, between 1958 and 1962, will once again study the urbanization of Campo Alegre.

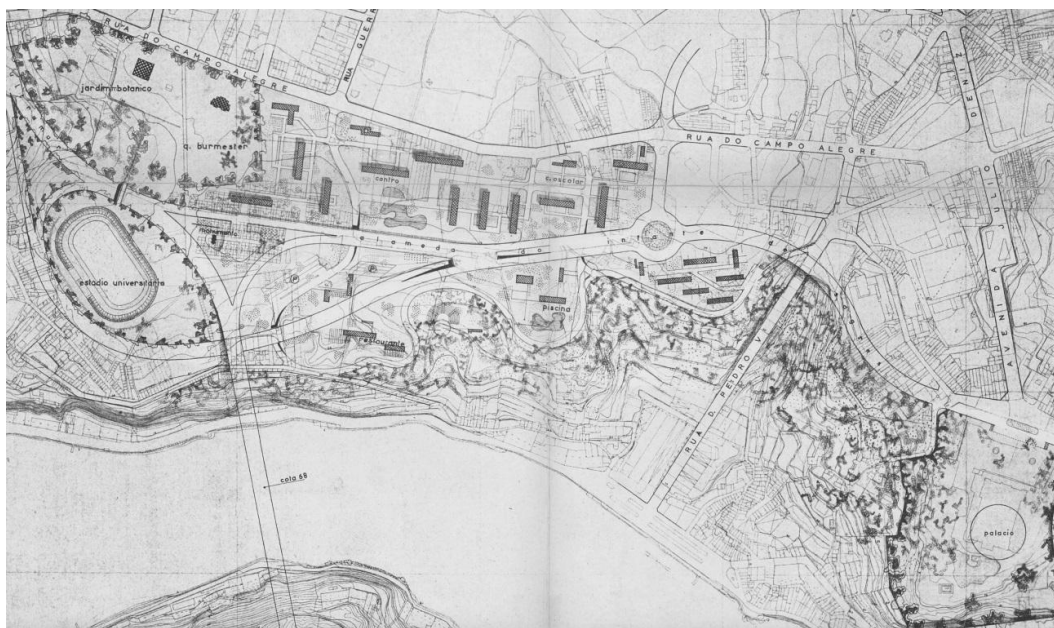

Figure 3. Preliminary Project (*Esboceto-Programa*, 1954).

Figure 4. Definitive Plan (Oliveira, 1969).

Place: a sum of private garden plots

The Urbanization Plan for Campo Alegre included two distinct areas of action inscribed in each other: one extensive regulated by general principles of urbanization and the other, smaller in size and inscribed, where the Plan proposed a “complete and radical system of urbanization” (*Plano*, 1955). This area, with deeper development, corresponded to Campo Alegre – considered by Januario Godinho as “a privileged territory” that “the new bridge over the Douro River and the associated road network, would certainly change completely” (*Plano*, 1955).

Campo Alegre’s site corresponds to the cliff on Douro’s riverbank, located at the point where the distance between the River’s margins decreases, just before the River’s mouth.

The area of the territory studied by the Plan is larger than 75 ha, facing the River over more than 1500 m. The boundaries are defined by Campo Alegre Street in the north, Douro River in

the south, Cristal Palace Garden (1865) in the east, and, in the west, the Botanical Garden (1875).

The general configuration of the site alludes to a polygon comprised of a convex section with a pronounced curve southwest and a sequence of ledges, facing the River that characterizes its perimeter to the east.

Campo Alegre is composed by two different topographical forms: the plateau, located at the top of the cliff, between 75 and 60 m; and the steep slope, between 60 and 0 m, accompanying the course of the River. In the south-west, this slope is characterized by a rocky mass and in the south-east, it is shaped by a sequence of natural terraces.

In 1952, the area of Campo Alegre was at the outer limits of the main urban areas, between the City center, at less than 2 Km, and the communities near the seaside.

Both the Campo Alegre Street, at the level of the plateau, and the road near the waterfront established important communication connections between these urban areas reinforced by public transportation (tram and bus) that also circulated through these routes.

In general, the land division in Campo Alegre presented a rural pattern. The territory was divided into large plots, organized in a system ingrained in Campo Alegre Street and on some ancient milestones; this system interpreted the local topography (Ramos, 2013).

In certain parts of Campo Alegre this rural pattern had turned into an urban one, namely with Campo Alegre Street, Entre-Campos Street and in the Arrábida Neighborhood.

Along Campo Alegre Street, some rural plots had been divided into new lengthy and narrow urban parcels, perpendicular to the street with a constant front dimension.

Entre-Campos Street was outlined through rural plots, by a group of local owners who proposed to transform their farming land into urban parcels where, years later, the State/Municipality constructed semi-detached and terraced low cost housing (Colônia Operária Viterbo Campos, 1915; Bairro Sidônio Pais, 1918-20, 1922-23).

Complementarily, near to an important industrial area at the time (Lordelo do Ouro), and very close to the rocky-mass, but away from the riverside, a working-class neighborhood, consisting of terraced housing, was being constructed - the Arrábida Neighborhood.

The population density, in average, was low hence Campo Alegre was a sparsely populated area due to the fact that building concentration existed only where the field system had been updated, while in the other areas, the buildings were detached and dispersed.

Campo Alegre was punctuated by poor and ephemeral constructions, to support agricultural and gardening practices, camouflaged in the landscape, and by a group of small palaces, disengaged from the rural surroundings.

In the 19th century, Campo Alegre was a place of sublime nature and picturesque qualities, where many foreign families of merchants and industrialists – including English, Danish and German – cultivated a Romantic lifestyle.

These families built their small palaces and gardens, with exquisite greenhouses, in existing rural plots. Many of the gardens, apart from native vegetation, contained special plant collections from all over the world, namely big trees which formed luxurious arboreal masses. These estates were: Casa Andresen, Casa Burmester, Casa Primo Madeira, Quinta da Esperança, and Casa do Gólgota.

Casa Andresen was purchased by the State in 1950/51 with the purpose to create a Botanical Garden (1951), a University Stadium (1951-53) and a series of residential and functional buildings for the University. Casa Burmester was also handed by the State to the University (1957) as compensation for the area reduction of the Botanical Garden, motivated by the necessity to construct the new road network associated with the Arrábida Bridge.

Therefore, in 1952, Campo Alegre was a huge greenery, composed of a series of private gardens between the Cristal Palace Garden and Botanical Garden. Campo Alegre's landscape was characterized by the estates of the small palaces, clashing with the low cost neighborhoods, the vast plateau, the steep rocky mass and the sequence of natural terraces, all largely cultivated and strongly arborized.

Through this territory, the Arrábida Bridge, as the second car crossing to be built in the City, would link the major coastline cities north and south of the Douro, transforming Campo Alegre not only into a new entrance of Porto, but also into a forced passage point for the main national highway.

Under these circumstances, the “Plano Regulador” (Figure 5), which summarizes the previous studies “Ante Projecto das Comunicações Regionais do Porto” (1945), “Ante Plano Regional da Cidade do Porto” (1946), and “Plano Geral de Urbanização da Cidade do Porto” (1947/48), all rendered by the local planning authority, programmed the City expansion for Campo Alegre in the following way (Garrett, 1952): i) identified existing public or private open spaces and defined them as being of public interest – the Cristal Palace Public Garden and the Botanical Garden; Casa Burmester Garden and some estates on the steep slope, namely, Quinta da Esperança and Casa do Gólgota gardens; ii) defined the traffic facilities in Campo Alegre, associated with Arrábida Bridge; iii) suggested the construction of a residential zone, where non residential buildings were only admitted in specific areas.

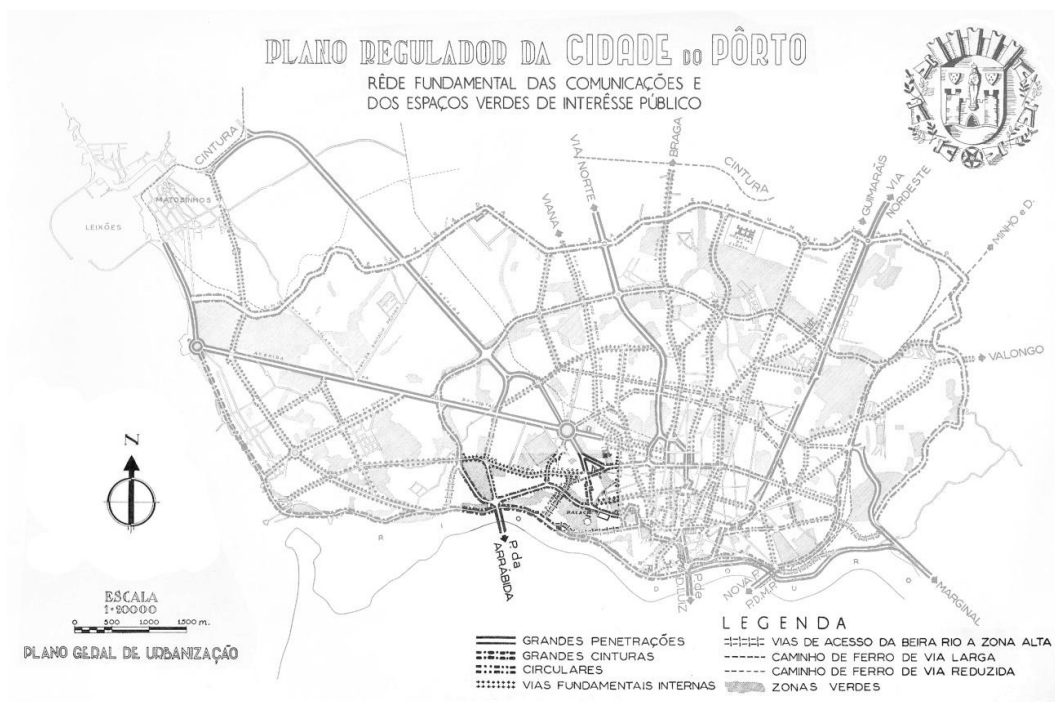

Figure 5. “Plano Regulador”: the proposed roadway network and the open spaces of public interest (Garrett, 1952).

Intent: a co-ordinated public park

The territory between the Cristal Palace Public Garden and the Botanical Garden was for Januário Godinho “of the greatest difficulty, in all aspects, due to constrains of all kind, consummated facts, that by a singular coincidence seemed to have met in order to render useless a rare opportunity for the future of Porto” (Plano, 1995). These restrains were: the rugged terrain; the open spaces of public interest; the location of Arrábida Bridge; the low cost housing ensembles; the commitments between the State and the University; the importance of the programmed road network; and the symbolic significance of the planned urban landscape – a fresh new image of Porto.

On this complex territory, Januário Godinho starts with the observation of Campo Alegre from the opposite riverside which would become one of the main viewpoints of Campo Alegre

after the construction of the Arrábida Bridge. From Vila Nova de Gaia, Januário Godinho might have read Campo Alegre as a sum of private garden plots. Through balancing this specific quality of Campo Alegre with the conditions present in “Plano Regulador”, Januário Godinho proposes the implementation of a co-ordinated public park, related to the new road system and the planned building ensembles.

Greenery

In the first drawings, Januário Godinho renders Campo Alegre as the “south park of the City” (*Plano*, no date). He foresees the entire territory coated with vegetation and restricts the construction areas to Campo Alegre Street and the surroundings of the University Stadium.

The proposal rendered buildings as elongated rectangles organized in a straight line, perpendicular to the river front, in an equally spaced layout. Taking into account this distributional pattern the scheme might have been organized with high-rise buildings attributing to Campo Alegre a closed architectural image of compacted vertical masses sited in an immense greenery, through which the major road network would be designed.

In the subsequent studies of this Plan, there was a progressive increase of the built area with consequent reduction of the open public space.

The main aim of “Plano Regulador” was to implement a residential area in Campo Alegre and although it pointed out some open spaces of public interest, the design did not include an open area of greenery, where anybody can go to walk, play, etc.

Therefore, this increase in density may reflect a gradual adjustment of the proposal to the “Plano Regulador” guidelines and/or a response to the financial burden that the implementation of the Plan implied for the Municipality (*Plano*, 1955). The draught of Januário Godinho required a global land expropriation which meant a huge investment of municipal funds that would need an equity return, incentivizing higher construction density.

However, even with considerable differences in land use between the diverse versions of the Plan, Januário Godinho never once deviated from his co-ordinated public park premise – the open space always dominated the constructed area.

The Plan stipulated that the construction of residential buildings, sponsored by private stakeholders, would be permitted only within the defined polygon according to the strict Municipality regulation. Apart from the building polygons all the remaining areas were defined as greenery for public use (*Esboço*, 1954).

In the words of Januário Godinho: “the overview [of Campo Alegre] will be a curtain of greenery, revealing by transparency various kinds of architectural elements. The entrance of the City will therefore feature a wide and majestic balcony projected over the river, overlooking the sea” (*Esboço*, 1954).

Traffic Intersection

Januário Godinho designed the road network at the exit of Arrábida Bridge based on the directives of the “Plano Regulador”. The proposed road network establishes the connections between the points referenced in the City Plan. However, the solution in Campo Alegre’s Plan deviates from that of the “Plano Regulador” in the way it solves the different traffic intersections.

The “Plano Regulador” stipulated from the Arrábida Bridge three road networks (Garrett, 1952): “Ultramar Avenue”, the western section of the City’s ring road, connecting the north of the country; the “new Avenue”, an extension from the Bridge to the North, connecting the City’s seaport; and “Infante de Sagres Avenue”, the eastern section of the City’s ring road, connecting the center of Porto. The “Ultramar Avenue” and “Infante de Sagres Avenue” were designed in continuity as a single gesture.

To design the intersection of the different road networks, Januário Godinho proposes a solution with the most modern research on traffic layouts; these schemes, which included

Spanish and Dutch press clippings about Detroit and Ohio intersections, were part of the Plan's study process.

According to the "Ante Plano Regional da Cidade do Porto" the road network in Campo Alegre should be extremely efficient – saving time, energy and money; allowing maximum performance in speed and traffic flow; improving the traffic circulation (*Anteplano*, 1946).

Therefore, Januário Godinho segregates the fast long-distance traffic from traffic of purely local nature. He seeks to eliminate intersections providing uninterrupted traffic flow by: always favoring intersections at different levels between main and secondary roads; only allowing the contact between them in specific designated points; and avoiding construction along the fast long-distance network (*Esboçeto*, 1954).

Based on these assumptions, the Plan proposed the following deviations from the scheme outlined by "Plano Regulador": i) canceled the "new Avenue" – Januário Godinho verified that the proposed road would create various intersections, something he intended to prevent (*Esboçeto*, 1954); ii) changed the type of traffic intersection at the exit of Arrábida Bridge – Januário Godinho noted that the proposed roundabout solution, was unsatisfactory economically and aesthetically. It entailed the partial demolition of the University Stadium and required the construction of a high retaining wall, a "real dam between the plateau and the slope of the Douro River" (*Esboçeto*, 1954).

For the traffic intersection, Januário Godinho rendered a flyover scheme (*Esboçeto*, 1954). With this solution, he proposed to divide the "Ultramar Avenue" and "Infante de Sagres Avenue" in a system which permitted so many passageways as the route directions generated by their direct intersection. This solution, although less compact than the roundabout one, allowed to deal with the territory constraints in an "elegant way" (*Esboçeto*, 1954).

For Januário Godinho this scheme was "natural, simple, open and, as far as possible, attached to the ground, eliminating the construction of stone walls, of colossal slopes" (*Esboçeto*, 1954), or multiple and costly works of engineering, avoiding the destruction of trees, reducing to the minimum the intervention on the University grounds and the demolition of houses in Sidónio Pais and Arrábida neighborhoods (*Esboçeto*, 1954).

Januário Godinho designs this flyover intersection in the following way: "Ultramar Avenue" and "Infante de Sagres Avenue", close to Arrábida Bridge, are divided each into two branches. One of these branches incorporates the Entre-Campos Street, crossing the Sidónio Pais Neighborhood and passing north of the University Stadium. The other, interpreting the convex shape of the territory through its pronounced southwest curve, is outlined between the southern boundary of the Stadium and the Arrábida Neighborhood; disregarding the area that lies between these two branches – characterized by University Stadium, part of the Sidónio Pais Neighborhood and different road extensions – this scheme divides the territory into two parts leaving to the north, the plateau, and to the south, the slope.

Therefore, by interpreting Campo Alegre's morphology and outlining the different qualities of its major topographical forms, Januário Godinho's design clings to the terrain.

This assertion is corroborated by the way the Via Panorâmica Route was designed on the slope, replicating the movement of the 60 m contour line and dividing the territory between the "Infante de Sagres Avenue" and the Douro's riverbank in two parts: the south where the steep slope inhibits construction and the north, an area which, although on the slope, still had acceptable construction conditions.

Januário Godinho's option of not proposing a pathway across the slope, connecting the plateau with the riverbank also reinforces this observation. A pathway with this direction would hardly cling to the terrain, so he does not consider it, in his design. Alternatively, the difference in elevation between the plateau and the riverbank would be solved by the elevators that would be included in the Arrábida Bridge's project.

Buildings

In the words of Januário Godinho: “[in Campo Alegre] the system of grouping the blocks [is carried out] according to the nature of the terrain” (*Plano*, 1955).

Regardless the building’s vocation, density of construction and housing type, which varied throughout the different phases of the Plan, Januário Godinho organizes the buildings according to the following principles: on the plateau, north of the “Infante de Sagres Avenue”, the type and shape of the buildings were always identical, high-rise rectangular elongated residential blocks (8-12 floors), and its organization followed a single principle of composition with the blocks placed parallel and/or perpendicular to each other. These buildings occupied the best view and solar exposure of Campo Alegre, constituting “luxury residential units” (*Plano*, 1955); on the slope, south of “Infante de Sagres Avenue”, the type and shape of the buildings were variable and its organization resulted “disarticulated for better adjustment to the characteristics of the terrain” (*Plano*, 1955). In the Preliminary Project, Januário Godinho proposed the construction of cultural, sports and leisure facilities along the Via Panorâmica Route: a municipal swimming pool, a restaurant and an amphitheater of greenery for outdoor performances (*Esboço*, 1954). In the Definitive Plan, the margins of the Via Panorâmica Route were occupied by residential construction for the middle class with the exception of a small area designed as a center of leisure and sport. The residential buildings were planned as 4 stories high blocks (eventually 8), with different shapes in plan and associated according to different strategies, suggesting the construction of small residential ensembles with different morphological characteristics (*Plano*, 1955).

Thus, the nature of the terrain not only influences the system of grouping the blocks, but also the type and shape of the buildings and housing categories, as if Januário Godinho recognized through the nature of the terrain differentiating characteristics that influenced the buildings and, in particular, the type of residential units.

This idea is stressed in the Preliminary Project by implementing the municipal swimming pool and the restaurant in special topographical points of the territory. These public facilities were designed for the ledges that characterized the south border of Campo Alegre. Sticking out over the riverbank, the swimming pool and the restaurant would offer panoramic views over the future bridge and the Atlantic Ocean.

Purpose: a territorial interpretation

Through this current interpretation, we may synthesize the following considerations concerning the “Urbanization Plan of Campo Alegre – Future Entrance to the City by the Arrábida Bridge”: i) the general idea of Januário Godinho’s Campo Alegre, deviates from the principles established by engineer Antão de Almeida Garrett, emphasizing different disciplinary perspectives on the meaning of Campo Alegre in the City structure; ii) the Plan constitutes a singular exercise that interprets the essence of place by prolonging and underlining the features that Januário Godinho considered to be its core qualities; iii) by the proposal of a co-ordinated park, the Plan prolongs the existing dominion of luxurious arboreal masses over the constructed area that was characteristic of Campo Alegre’s setting in 1952; iv) the gardens, beforehand fields, are transformed into a greenery system, linked to the existing public gardens (the Cristal Palace Garden and the Botanical Garden) and related to the new road network and proposed building ensembles; v) the park’s design outlines the existing morphology and altimetry qualities of the territory, organizing the buildings and the major road network through their reinterpretation; vi) by the introduction of a public park theme, the Plan highlights the predisposition of Campo Alegre, through its topological and geographical qualities, to assume the special condition of a public space in the City of Porto.

These conjunctions permit the understanding of a certain architectural way to interpret the notion of place by identifying the evolution and persistence of a territorial purpose.

The Plan does not copy a model or an old solution, on the contrary, it recognizes the primary structural properties of Campo Alegre – respects its location, general spatial configuration, and its synthesized image – interpreting it in a contemporary way. Consequently, the proposed solution conserves the identity of the place emphasizing its material substance, shape, texture, and colour - its Romantic environmental character.

Therefore the Plan seems the outcome, in one hand, of the extreme attention Januário Godinho pays to the place, and on the other hand, of a sheer spatial force of Campo Alegre that guides Januário Godinho towards the accomplishment of its essence in a new historical context.

Is there a transversal organic pattern? Favela and its diachronic relations

Vânia Loureiro, Valério Medeiros

Abstract. *This paper explores Favela's spatial configuration within contemporary city searching for a diachronic relation in its complexity. And as an informal and organic space, favela must be observed by its collective emergent and spontaneous actions. It is important to understand its specific organic behavior as responsible for the inherent complexity and enormously meaningful for urban quality. To explore these similarities in organic form, a comparison is made between medieval Portuguese towns, Brazilian colonial cities, and contemporary favelas in order to infer diachronically the existence of a common configurational type. Space Syntax is the theoretical and methodological approach adopted. Findings show that favela as definition of a city space is much closely related to its configuration than with its socioeconomic status. Its organic genesis and spontaneous development are responsible for space qualities, and so, any settlement without it can't be consider similar. There is also, a transversal organicity which forbids favela to be considered an innovative (in)formal phenomenon – it takes part in the organic form genotype. The space being defined as Fractal and Synergic – internal scales relating in harmony, being complex and spontaneous – justifies its less immediate seizing but allows more intuitive use of space and more natural paths.*

Key Words: favela, organic form, spontaneity, configuration

Introduction

The present paper focus on favelas spatial configuration aiming to understand it not only as a contemporary city phenomenon, but also, as part of organic and spontaneous city form through history. It seems that favela points out an original spatial logic due to its scale in cities today. But it is intended here to explore whether it is effectively new in urban space or not, considering its informality but also its self-constructing nature.

For that reason a comparative study is conducted through this paper, in order to comprehend if informality behaves similarly in its spatial organization (if it can be named after favela all the times, as we commonly see), and if its configurational patterns are related to other self-constructed settlements. The actual planning logic frequently is far more simplifying than these complex structures, and so, already in its genesis, favela tends to be a misunderstanding complex space. Therefore the interest of this comparison and analysis is also to state what appear to be successful patterns in space when such complexity is allowed. Irregular city areas tend to gain from spontaneity what top-down (illegal) processes can offer them. This is the hypothesis to explore.

Favela is also city, despite its differentiated rules, its proper rhythm and crazy dimensions (Jacques, 2001) that apparently foreclose legal standardization. The complexity in space and formal rules not belonging to top-down methods in city brings favela close to incomprehension. Mostly due to its self-construction and self-organization spatial structures (Sobreira, 2003). Its *modus operandi* is bottom-up and that explains its difficulty of perception through top-down perspectives. This city is informal but also spontaneous and emergent, and above all it's a space belonging to its own time, creating itself through a roll of individual actions collectively driven by negotiation (Johnson, 2001).

Historical relation among organic settlements seems to interest as a way of studying *favela* not as a new element in city space but as a proper type of space in city, since ever. It is intended to test the hypothesis that once self-constructed space presents common patterns in its configuration despite its epoch or even cultural context. The option for Medieval Towns deals with the symbolic appeal of such cities once most of them are highlighted paradigms of the organic form, ideal to confront in the search for a diachronic relation. As well as the original colonial sites in Brazil, being another moment in organic city production.

Despite all its problems associated with social, spatial and symbolic segregation, *Favela* represents a complex living space, constantly being adapted. Based on this, the following paper will focus on studying the elements these forms contain for such a resilience and quality, why this natural implicit order appears in spite of the apparent “chaos”. This work is funded on the premise that contemporary *Favela* is nothing but a particular moment in the organic process for city space, as for its connection to the intrinsic knowledge of creating space that tend to go beyond time and History (Guerreiro, 2010).

Figure 1. Different spaces with similar configurations (a: Piódão, Portugal; b: Rocinha, Rio de Janeiro, Brazil; c: Manarola, Italy; d: Santorini, Greece) (source: Google Images).

Figure 2. Organic illegal Settlement: Favela (Morro do Timbau in Rio de Janeiro) (source: Google Maps).

Figure 3. Illegal Allotment (Sol Nascente in Ceilândia - Brasília) (source: Google Maps).

The set of images in Figure 1 shows clearly this continuity in a constructing and urbanizing process: it deals with the similarity of an organic pattern through time. Santorini in Greece, Rocinha in Brazil, Piódão in Portugal or Manarola in Italy, just to mention a few, are great examples of culturally and socially distant contexts but apparently similar in configuration, e. g., the way in which parts of a city are associated, producing specific relationships.

In this paper informal means everything which is not official or legally regulated, as in the construction of *Favelas*. But informal might also mean being close to a specific context and acting naturally within it (Houaiss, 2012). It can also mean a space being prefigured without implicit rules from an urban plan. It is informal because it is not following legal rules but natural ones, self-organizing itself (Salingaros, 1998). It turns “spontaneous” as it behaves emergently – “spontaneity” being an “implicit will determining itself to act” (Abbagnano, 1998) and emergent the evolvement process provoking it. So, when *Favela* and informal settlement appear to be synonyms, in the context of this research, there’s a “spontaneous” and emergent process from behind, guiding the resultant urban form. This leads to the argument about different types of illegality and the will to relate *Favela*’s concept strictly to bottom up order, once irregular settlements, as allotments, have nothing similar to organic displacements (Figures 2 and 3). It seems important to state such perspective because commonly *Favela* is mention as a social and economic status and not related to a specific type of form in space.

In order to achieve the aims of this discussion, the paper is organized in three sessions. The first one deals with methodological approaches, presenting how research was conducted through a comparative strategy in order to verify the possible existence of similar patterns. The second part takes care of the discussion about *favela*’s form by comparing different settlements and searching for patterns in space organization. It intends to bring form as an argument to distinguish illegal urban areas. Then, the third and last session discusses the results of the comparative process with the 22 study cases, from different epochs, in an attempt to observe spatial patterns in space through history. This will ensure the differences established in the previous part explaining space in its various organizational orders.

Methodological Approach

Regarding the theoretical, methodological and instrumental aspects, the work is guided by The Theory of the Social Logic of Space or Space Syntax (Hillier and Hanson, 1984), based on the Axial and Segment Maps (which represents the potential accessibility of a line according to its topology in the urban system) from each case study. Structured on a systemic perspective, Syntax intends to relate space and society, assuming an intrinsic relationship between both.

Space, understood as a social feature, is at the same time caused by and the cause of certain social dynamics – therefore it can be seen as dependent and independent variable (Medeiros, 2013).

The above mentioned maps (linear representations of street systems, considering the smallest number of the biggest lines) allow to quantify and observe the potential performance of space concerning its topological relationships. The obtained values are converted into a chromatic scale that distinguishes different levels of potential accessibility in the network, resulting from its configuration (Medeiros, 2013). The analysis, developed in Depthmap® software, offers variables (cf. Holanda, 2002; Medeiros, 2013) and some of them are relevant to the comparisons intended here: Global and Local Integration (the level of accessibility analyzed globally – when the system as a whole is considered – or locally – when only the nearby lines are processed), Connectivity (number of connections in each axe of the system), Number of Axes, Mean Depth (what is related to the number of steps which is requested, in average, to reach each line from all the other lines in a system; due to distinct connection types and the distribution of lines, the system can be “deep” or “shallow”), Line Length, Synergy (the correlation among local and global properties, based on the correlation between Global and Local Integration), Intelligibility (legibility of a system from any point, considering the correlation between Connectivity and Global Integration), Segment Mean Length (dimension between two consecutive nodes) and Angular Choice (the priority chosen segments within all system routes, covering small angle deviation).

In order to explore the issue, the analysis considers 22 case studies: the historical grids of Lisbon, Porto, Santarém, Óbidos, Marvão, Castelo Novo, Castelo Rodrigo, Linhares, all in Portugal; the colonial sites of Tiradentes and Goiás Velho in Brazil; and the contemporary Favelas Cova do Vapor in Portugal, Vidigal, Jacarezinho, Providência, Timbau, Heliópolis, Jaqueline and Jardim de São Luís in Brazil, and yet, the partial maps of Favelas in Luanda (Angola), Beira and Maputo (Mozambique).

Is there a spatial pattern for favela?

Paola Berenstein Jacques assumes in her book, the vision of *Favela* as a physic labyrinth and deals with the concepts of implicit knowledge and tenure in informal space dynamics to walk through it understanding the essence (Jacques, 2001). Christopher Alexander also mentions (decades before) this common ability to build within specific emergent and ancestral patterns implicit to man’s action (Alexander, 1979). This happens due to the “bottom up” process that seems to be implicit in the building action as in the effective acknowledgement of space to users. At first sight its complexity appears difficult to read, specifically through formal rules learned from modern urbanism that simplify spatial relations (Salingaros, 2006).

Being an implicit order, fractal geometries are responsible for the organization of organic cities as they are in nature and life, and rules as self-similarity in these spaces might be the key to understand this unplanned order (Guerreiro, 2010). And so, favela as an informal and emergent process, seems to have a particular behaviour in space, as follows.

Figures 4 and 5 are the first step to understand the presented study cases and the result of a comparison based on space syntax analysis. Segment and Line Length (consequent from segment and axial maps) are useful to understand each system’s dimension, being then aware of its differences in scale. As we can see, there are very distinct sizes in the cases chosen but once looking at favelas, it remains in a row, showing similarities in size. The only unequal case is Sol Nascente, illegal allotment in Ceilândia, Brasília, whose line and segment length are far from the other irregular settlements. This uncovers the particular reason why this case was chosen: often called *favela*, Sol Nascente seems to have a distinct spatiality when related to organic illegal spaces, and so, it is intended to explore spatially, the conceptual discussion above.

The Integration of a system means its accessibility potential from all its parts to all its parts. Therefore, as much integrated a system is, the easier its access appears to be. Figure 6 shows

precisely the Global Integration levels of all studied cases, after normalization (a mathematical technique to reduce scale differences among systems and reinforce similar properties or differences despite dimensions) and the Figure 7 the Local Integration (the same properties analysed at a small scale in the system). This might mean a true configurational similarity among settlements, once we can see in both graphics a permanence of close values. The only distinction in Local Integration is Sol Nascente its values appear higher than the rest which can be related to its straight line grid that rapidly connects the local parts to each other despite a truly inefficient relation at global level due to the innumerous dead ends (Figure 8).

Figure 4. Line Length (source: Author).

Figure 5. Segment Length (source: Author).

Figure 6. Global Integration (source: Author).

Figure 7. Local Integration (source: Author).

Figure 8. Sol Nascente's Axial Map (source: Author).

Figure 9. Synergy (source: Author).

Figure 9 presents Synergy levels from the studied *favelas*. Synergy is about the interaction ability between local and global levels of a particular system, which means a way to understand how small centers do interfere with global centralities – how the parts are affecting the whole. Looking at the presented values Cova do Vapor seems to have the highest synergic dynamic within its system, and Sol Nascente appears to have clearly the lowest. Vidigal and Providência are the next lower cases, which might be related to its topography once they seem to be the most extreme situations (hilltop *favelas*) in this sample. Apparently its synergy tends to decrease when declivity rises because some connections turn impossible to emerge. Nevertheless Sol Nascente is a very particular case, it presents itself in a much less declivity situation and the absence of interaction within its parts appears to come precisely from its design, created as a row of dead end streets through different directions. Observing its axial map (Figure 8) it is possible to understand the impossibility of such characteristic in this space – the parts are barely interacting with each other.

Figure 10. Intelligibility (source: Author).

Intelligibility means the ability to perceive space wholeness while standing in a single part of it, its easiness for being read. Looking at the Figure 10 it is possible to see that values tend to be low in this case: favela's complexity and spontaneity are responsible for a variety of spaces that forbid a clear perception at a first moment. This is possibly the greatest reason why it is so frequently considered labyrinthic (Jacques, 2001): protection from the outside is a demand for the space dynamics, therefore, it cannot be read easily. The clear perception of space is left only to the inhabitants, which explains such small values. But again, Cova do Vapor seems to have the highest levels: despite its complex structure, the small dimensions of the settlement (Figure 14) tend to favour its perception (as the correlation study in the next session will show). Luanda, Vidigal and Sol Nascente have the lowest values. Once again the topographic situation of Vidigal appears to be its greatest argument, causing its fragmentation. Luanda, on the other hand, seems critical by its dimensions (1385 axes) and depth (16.81), its size reveals a much deeper and complex structure. As we will see scaling properties of favelas frequently tend to increase some of its characteristics in the growing process. In Sol Nascente the opposite happens: its straight grid and dead end streets emphasises an inefficient communication among parts, and so, a difficult apprehension of space as a whole. A possible lack of organized complexity (Salingaros, 2006) in an illegal space designed to enter a regular system of allotments as seen in Figure 11, when the settlement's axial map is shown connected to its closer context – Ceilândia. The top-down dynamic is based in Brasília, not only in its original plan but also in its periphery – irregular areas like Sol Nascente only seem to replicate a model in a clear attempt to interact.

The comparison of these maps and values expresses a clear similarity among most of the cases which reveals the hypothesis of the existence of favela as a particular set of spatial patterns. A particular pattern of space organization for what we call favela. Sol Nascente is clearly excluded. Its lack of synergy when it seems to be one of the greatest advantages of spontaneous settlements, responsible for a successful internal performance in space, accuses the

presence of an entirely different process and order (top-down). Figure 12 shows, complementary, how the Latin America's biggest favela (Furquim, 2013) is much more likely to be a huge complex of illegal allotments whose spatial dynamics respond to other specific rules, possibly those of land regulation.

Such finding allows rethinking favela as a concept used to mention illegality in urban space and its socio-economic issues in a global sense, without questioning its genesis or configuration. The absence of spontaneity in space conformation tends to create inorganic and less flexible configurations, a very different situation from those seen before. Urban form entering as a factor in diagnosing illegal areas points out the impossibility to name such different spaces the same. Favela is here defended as the complex and emergent phenomenon that results in organic spaces built spontaneously.

Figure 12. Streets in Sol Nascente (source: Author).

Favela aligned diachronically to historical city

The previous analysis as stated the tendency to assume a specific spatial pattern to favela whose spontaneity and emergency are essential characteristics and inorganic urban forms tend to be excluded. Based on this it is possible to move towards a diachronic study inquiring favela's relation to organic historical city.

It is believed in an organic process belonging to a long tradition in city form, connecting medieval towns in Portugal to colonial cities in Brazil. Excluded by modern thought where its scientific principles were looking for a rational and orderly perspective (Salingaros, 1998). In

contemporary city, favela seems like a similar phenomenon, far from the top-down dynamic of formal system. And so, the data from studied favelas is compared to medieval towns in Portugal and colonial cities in Brazil.

Analysing at first the settlements dimensions it's possible to observe a clear variety in number of axes (Figure 14) as in line length (Figure 13) proving the scaling differences one could forecast in such a comparative (diachronic) work. Towns and Favelas are substantially unequal in dimensions and commonly it depends on various factors as population, available space and site specificities, or even cultural differences (as in medieval Christian public space in opposition to Islamic one). Nevertheless these metric differences are not impeditive of a similar structure for spatial relations in space. Global measure for Integration (the accessibility potential in space), when normalized to observe topologically without its metric specificities (Figure 15), shows an apparently strong similarity in space accessibility as a whole.

Local Integration (Figure 16), meaning the same accessibility potential but at a local scale (as in a district scale), points also out a pattern of movement similar through the Portuguese towns and the Favelas. Values vary between 1.81 and 1.1, which doesn't seem a meaningful distance to the research. It is also important to state that Óbidos is the only town expressively more accessible at a local scale, but very close to Santarém is Heliópolis already (São Paulo's Favela). The less integrated space is Morro da Providência in Rio de Janeiro.

The internal dynamics of analysed systems is also possible to observe through Synergy, a correlation measure which relates Local and Global Integration in order to evaluate how they seem interdependent or not. In this case (Figure 17) there seems to be a pattern of good synergic spaces in the sample, despite these three lowest cases, Medieval Lisbon and Providência and Vidigal, two top of the hill Favelas in Rio de Janeiro. Another curiosity is Cova do Vapor, an illegal settlement in Portugal, being within the most synergic spaces, which seems to indicate that despite epochs, organic spaces behave similarly.

Figure 13. Line Length (source: Author).

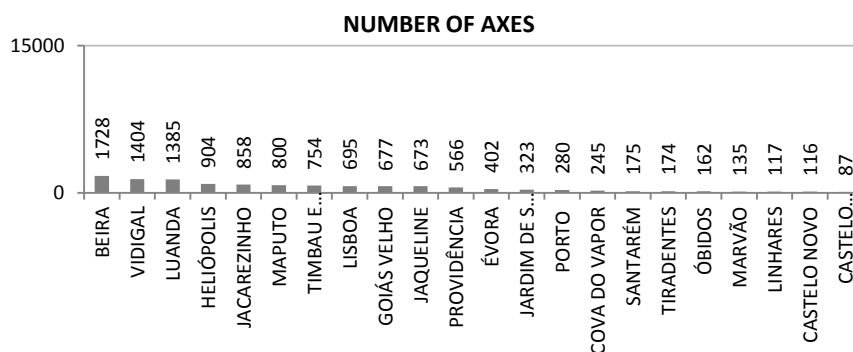

Figure 14. Number of Axes (source: Author).

Figure 15: Global Integration (Normalized values) (source: Author).

Figure 16. Local Integration (source: Author).

Figure 17. Synergy (source: Author).

The long argument in this text about complexity in Favela as in historic towns finds another good issue in the study of Intelligibility (Figure 18). Intelligibility is the ability to read the whole space by standing in just one point of it, and empirically is clear the difficulty to understand that easily a space like Vidigal or old historical Lisbon. That is why the values present such low result. Although, this specific case proves a clear difference between contemporary Favela and old towns: the old settlements are much easier understood than nowadays Favelas. Which is why the correlation between Intelligibility and Number of axes (Figure 19) appears next in the sequence: old towns are much smaller, and Favela's scale turns it deeply difficult to apprehend directly. The result is a 54% correlation between the dimension of the system and Intelligibility, meaning that size highly explains (c.f. Medeiros, 2013) the low levels in Favelas.

In consequence, the same process was repeated to Mean Depth, a measure that explains segregation in space, how difficult or easy it can be to access a specific axe in the system (Medeiros 2013). Settlements can be deep or flat depending on the high or low result, and it makes comparison possible in the sense of seeing space as a labyrinth or not. In this case, as Figure 20 can shows, Favelas are much deeper systems than old Portuguese towns. Nevertheless, such a reality can be again explained by the system dimension correlation (Figure 21): Space tends to be more labyrinthic as bigger it gets. The same structure of spatial relations can be more complex as it increases in scale.

Figure 18. Intelligibility (source: Author).

Figure 19. Correlation between Intelligibility and the number of Axes of each case (source: Author).

Figure 20. Mean Depth (source: Author).

Figure 21: Correlation Between Mean Depth and the number of Axes (source: Author).

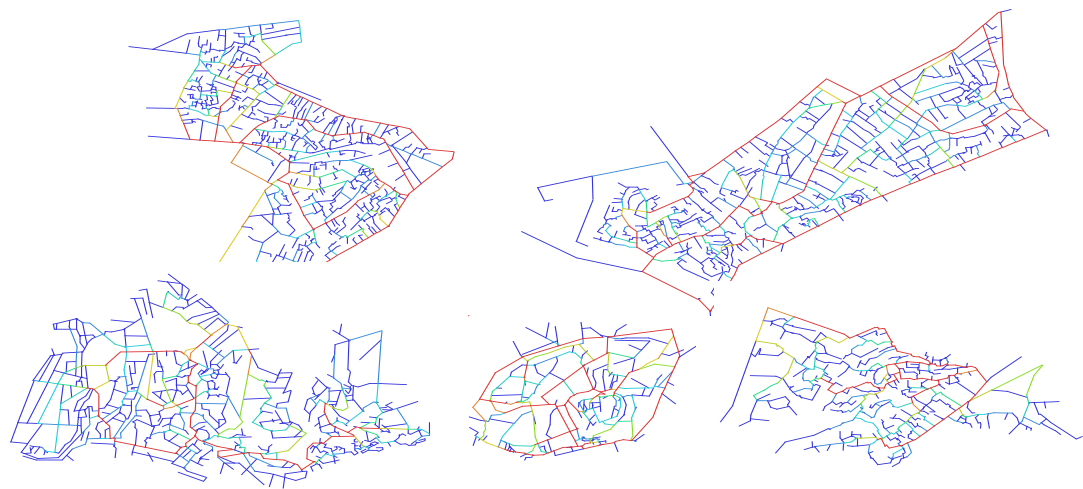

Figure 22: Angular Choice Maps (Top: Timbau and Jacarezinho; Bottom: Lisboa, Porto and Providência) (source: Author).

Finally, the image above shows the Angular Choice, an analyses that permit to understand how people tend to move in space. Choice means analyzing the potential for a street to be chosen within all the routes in the system, and so it can give us a good acknowledgement of how space is used. Favelas tend to be seen as labyrinthic spaces in the sense that it seems impossible to clearly walk through it. Looking at the images above (Figure 22) one can observe the clear structure of chosen axes for internal routes in space: all space is covered by an amazingly hierarchical net of paths. The complex space shows clearly here its self-organizing potential, and the similarities among epochs. The Angular Choice maps are a very important argument to prove the walkability of space and also the similarity between Favelas and Medieval Towns. There are clearly more used routes in each space, and the maps prove how much the space is (potentially) covered by movement and how connected these routes seem to be.

Historically and culturally different settlements present configurational similar relations (Medeiros, 2013). This is the critical point in the research: diachronically the organic pattern was responsible for the continuum know-how of making city and organizing its space. The proved similarities allow us to believe in an effective timeless way of building (Alexander, 1979), inherent to human beings and to its natural ability to adapt. Spontaneity and Emergence apparently lead the way to Natural Complexity (Guerreiro, 2010) existent in the unplanned or implicit organic spaces (Kostof, 1999). But remains the question: Is it possible to plan this type of organicity? This study points out the existence of a possible way to acknowledge these complex geometries unseen through simple observation. If Morro da Providência and Medieval Lisbon are equally chaotic seen from the outside and present the same self-organized rules in their spatial structure, these recognized patterns are potentially the clues needed to understand its spatial dynamics.

Conclusions

Favela is defined as a complex form dependent on a spontaneous genesis and a bottom-up order, as observed through the settlements comparison. Favela is often mentioned as a socio-economic particular reality in city, frequently not mentioning form and urban space. This paper intends to point out a distinction based on urban form issues: believing in space as influenced and influencing at the same time, organic favela and irregular allotment represent very distinct social dynamics. Favela, as spontaneous and emergent, acts in synergy and according to scale developing a dynamic relation in space within its parts.

Despite similarities, medieval settlements have smaller street system and its axes are commonly longer, resulting in a much complex space in Favelas. This emphasizes the hypothesis that scale has an important role in comparison: organic spontaneous structures present high levels of synergy, which appears to mean the existence of an harmonic relation among lower and higher scales in a system. That suggests that to grow it must also get more complex to ensure the needed levels of hierarchy the organic space need to work efficiently. Self-organization seems to be the origin of such amazing dynamic in space.

Contemporary city leads to absolutely different scales and dimensions, but the processes it is emerging from are possibly the same through city history. This is clearly a starting point and an experimental work, but findings surely point out directions to future studies: Illegal areas in city are not all the same (despite their similar socioeconomic problems), but those of organic and spontaneous genesis present such potentially successful space properties as the older towns we often are amazed to meet.

The 'Ilhas' of Porto and 'self-improvement urbanism': the inhabitants as engine of urban transformation

Natasha de Sena, Kees Doevendans, Sophie Rousseau

Alterra Research Institute, Wageningen University, Eindhoven University of Technology, The Netherlands. E-mail: natasha.desena@wur.nl.

Abstract. *An 'Ilha' in Porto is a typology of low cost housing which spread within the city in the 19th Century as a result of the industrial development. The extremely small dwellings (around 4x4m) were established within backyards of middle class houses, connected to the street through a narrow corridor. Despite all public trials of destruction, more than 1.000 'Ilhas' still shelter more than 13.000 people within the city of Porto. The subject of this article is the analysis of the morphology of the 'Ilhas' of Porto, Portugal. The objective is to illustrate what the typology currently means for its inhabitants and for the urban space and propose methods of improving their living standards. The social and spatial dimension of the 'Ilhas' as an 'assemblage' of the city determines the research method, focusing on a) an analysis of the morphology and typology of a selected cluster of 'Ilhas' in different scales; b) participatory research involving the inhabitants, including interviews and observation of daily practices and community values.*

Despite the low quality living conditions, the inhabitants of the 'Ilhas' show an impressive attachment to their living space, forming a strong community. This quality is used as a foundation for the 'self-improvement' urbanism, where the community operates as the main engine of the urban transformation.

The main finding of the research is that the 'Ilhas' could be an inexpensive solution for the current housing crisis through the further development of the 'self-improvement' urbanism. This innovative approach includes strong public participation and an innovative position of the planner within the process.

Key Words: *Ilhas, social history, morphology and typology, urban anthropology, self-improvement urbanism.*

The morphology's historical development

The Ilhas have an unique typology within the urban tissue of Porto. This typology is a result of several specific events within the historical morphological development of the Porto, in physical, economic and social aspects.

During the 18th century Porto faced its first large population growth, a consequence of the economic growth (Teixeira, 1996, p. 19) caused by the success of the Porto wine and trade development with England (Porto Vivo, 2005, P. 27). In 1732, the city had around 30.000 inhabitants, and reached more than 60.000 in 1787. Porto went through a densification process within the boundary of the medieval walls, and only after 1760 the city expanded, in a planned development, to outside the former borders.

In 1763, the governor João de Almada, later followed by his son Francisco de Almada, started the expansion plans for the city, in a highly centralized decision making process (Monteiro, 2009). Concerning urban morphology, the 18th century was very important for the city. Under the governance of the *Almadas*, new streets were opened or restructured, and new public space was created in the oldest urban area (Rio Fernandes, 2005, P. 4). The economic growth was translated into a clear urban expansion. The medieval walls lost their military defence value, as a result of the development of artillery, and were therefore destroyed in almost all its length (Rio Fernandes, 2005, P. 4). Four axes were built: they irradiated from the old centre and pointed towards the main agglomerates of the outside region (Figure 1).

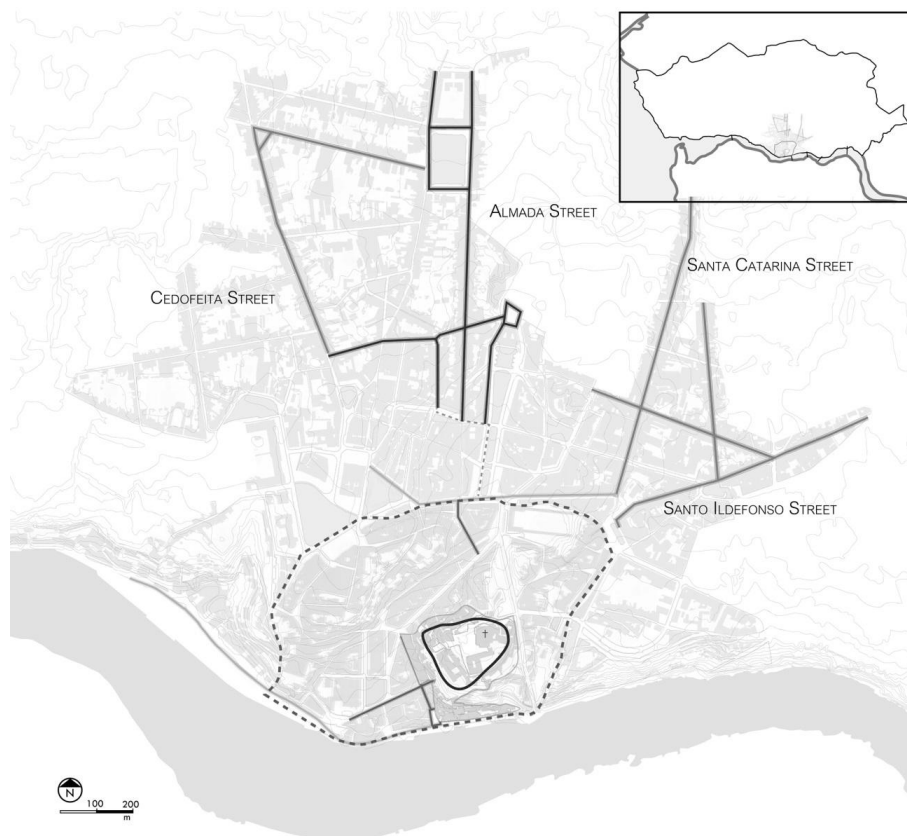

Figure 1. The Almada expansion: Porto in 1813, occupying the new axes of expansion.

The expansion plan of the Almadás in the 18th century defined several future aspects for the city of Porto, including the development of “Ilhas”. The new axes of development were then slowly occupied by new plots, where new dwellings for the higher classes were built. Besides defining expansion lines, the plan also created norms for defining the new plots. The focus of the plan was the street, and not the urban block (Ferrão, 1997). The pattern for new urban plots defined plots with narrow front lines and deep depth, making the maximum use of the new street infrastructure in its length. The façade of the plot was mostly 5,5-6 m wide and very long, sometimes reaching 100 m of depth (Teixeira, 1996). The dwellings had long backyards, differing from the pattern of the old compact medieval city (Figure 2).

Figure 2. Map from the Almada plans. The long plots were placed along the new street, without a pattern of urban block (Nonnel, 2002).

After a period of low population growth caused by the French invasions (1803-1813) and the civil war (1832-34), the city started to grow again due to the industrial development and the arrival of immigrants from the countryside. Between 1838 and 1900, the population of Porto went from 59.000 to 168.000 inhabitants. In 1911, Porto had expanded its surface and had a population of 194.009 inhabitants (Pereira, 2003, P. 140).

According to Rio Fernandes (2005, P. 6) there are two main consequences for the high levels of population growth of this time. Firstly, the residents of the oldest parts of the city, who had financial sources, moved to large housing areas in the suburbs. The empty houses left behind were then occupied by the immigrants, and the centre faced a continuously densification of its buildings. Secondly, the main destination of immigrants, especially the ones coming from the rural areas, became the long backyards of profit seeker property owners, usually located nearby industrial areas. These are the *Ilhas* (Figure 3).

Figure 3. The main street, the front middle class houses and the *Ilhas* occupying the backyards.

The *Ilhas*

The new working class needed a new solution for low cost housing. In this context, the *Ilhas* appeared in Porto. *Ilha* is the Portuguese word for island, and that refers to the relationship of these dwellings with the urban space. They occupy inner spaces of the city, like small infill islands, surrounded by buildings from all sides. Porto 'grew inwards' (Figure 4), increasing its density through the development of the *Ilhas* (Pereira, 2003).

Besides, the urban plots had between 5,5-6 m of façade and a deep depth, and these long and narrow backyards were viewed by the inhabitants as an opportunity. Responsible for the construction of the *Ilhas* were not large developers, but small entrepreneurs with limited sources, namely the inhabitants of the front houses themselves. The higher social classes were, at this time, moving to even further from the centre, and the first expansion areas were occupied by the lower middle class (Teixeira, 1996).

The *Ilhas* were small scale and low quality constructions, with the only objective of providing cheap and fast housing. Most of the *Ilhas* were built not at once, but gradually, in a process of internal growth of the city through occupation of the inner space of urban blocks. The primary typology of the *Ilha* is composed by rows of small and single-layer houses, built in the

back side of middle class houses. The majority of the Ilhas had around 20 dwellings, with a single pavement and average size of 16 m². The small houses of the Ilhas were then built based on the façade space, forming lines of houses and corridors through all plots. The access to the street was usually made through a small corridor on the side of the middle class houses which faced the street (Teixeira, 1996). The sanitary facilities were minimal, shared by all houses, and usually located on the back of the plot (CMP, 2000). The Ilhas have all kinds of variations, but the original typology, which is still rather common, is showed on Figure 5.

Figure 4. A morphologic comparison between the medieval city core, the 18th century expansion and the Ilhas: the city grew towards the inner-block space.

Within the most critical period of city growth, between 1878 and 1890, more than 5.000 dwellings in Ilhas were built. In 1899, the Ilhas were home to 35.000 people, 30% of the total population (Pereira, 2003). The city had around 168.000 inhabitants at that time (CMP, 2000). The largest concentration of Ilhas was on the eastern part of the city, near the industrial areas. Nevertheless, Ilhas could be found all over the city, but always with some proximity to an industry.

Figure 5. Ilha in detail: Impression of the dwelling size and how the residents outline the inner divisions of their homes.

Due to its construction characteristics, such as reduced size, cheap and low quality materials, common sanitary facilities and lack of sewage system, the Ilhas soon became famous in the city as insalubrious and sickening places (LEMOS, 1914). The high density of these housing areas, together with the lack of hygiene and sanitary facilities was a strengthening to the common diseases at that time, and helped the proliferation of tuberculosis, cholera, typhus and the bubonic plague (CMP, 2001).

The current situation

During the 200 years of Ilhas' history, several public programs have made trials to extinguish them. Most programs involved demolition of Ilhas and relocation of people to suburbs. The several programs of relocation of inhabitants through the years only changed the social segregation pattern in Porto. The form of segregation with the working class occupying central spaces, had a shift to a periphery pattern segregation.

In 2003, more than 40.000 people were living in social neighbourhoods (Pereira, 2003, P. 145) built to shelter the relocated inhabitants in the second half of the 20th century. Many of these neighbourhoods are currently considered 'problem areas' in the city due to high levels of criminality, and are now being demolished by the authorities. According to Pereira (2003, P. 145), "most probably, around 20% (...) of the population of Porto have inherited living conditions from the housing solutions – and lack of solutions – that were a consequence of the industrialization and urbanization process of Porto".

Nevertheless, after all the trials from the authorities to eradicate the Ilhas, they still exist in the city (Figure 6). Information available in 2001 pointed to an estimation of 13.500 people living in Ilhas, plus more than 6.500 people in similar living housing conditions (Pereira, 2003, P. 145). "In the classic form, there are still in the city of Porto 5.900 houses in Ilhas" (CMP, Pimenta; Ferreira, 2001).

Figure 6. Ilhas in 1940 (CMP, 2001) and 2012 (source: photo by author).

Problem definition

The Municipality sees the Ilhas, undoubtedly, as a major urban problem. They have demolished the majority of Ilhas located in public ground in the last years. In June 8th, 2003, it could be read on the first page of the newspaper “O Comércio do Porto”: “Last municipal Ilha breaks down this month” (Cited in Pereira, 2003, P. 147). The authorities declare that ‘the large and critical problem of the private Ilhas in highly degraded conditions persists’ (CMP, Pimenta; Ferreira, 2001). The problem, according to the authorities, is formed by the high degraded conditions of the dwellings, unhealthy standards, the low income of the inhabitants and ‘the expectations of future profit with the liberation of the plots situated in privileged zones of the city’ (CMP, Pimenta; Ferreira, 2001).

Nevertheless, the demolition of Ilhas increases the demand for social housing. The higher demand conflicts with the current plans from the Municipality to demolish a large amount of the social housing buildings in the suburb of Porto. Both demolition plans, concerning Ilhas and social housing, are not followed by a plan of approach for relocation of inhabitants, resulting in a larger social problem. Furthermore, there is already a lack of social housing. Not only social housing for the real poor and needy families, who manage to be selected by the municipality and located within a social program. But a lack of affordable housing, with a minimum of living quality, for many inhabitants.

Objective

The Ilhas form an embedded living typology in the city of Porto, which survived destruction trials for centuries. Away from the judgmental description of the Ilhas as poor and undesirable spaces in the city, the objective is to illustrate what the typology currently means for its inhabitants and for the urban space and to propose methods of improving their living standards. Given that there is need for housing, how could the Ilhas represent a solution for the current social housing problem, while improving the living conditions of its inhabitants?

Methodology

As guiding principle in the further morphological research of the Ilhas figures the concept of ‘assemblage’. In morphology we see the struggle between holistic-universal approaches aiming at historical-organic patterns of the city and layered or piecemeal approaches, that make the city a collage of palimpsest. Assemblage, as applied in (human) geography, takes as point of departure the ‘contingent, non-necessary coming together of various phenomena, actors, institutions, or processes to form a stable bundle of relationships and capacities’ (CASTREE et al, 2013).

For the research of the Ilhas this has been translated into a more practical than theoretical working method, based on the principle of ‘going there to see, learn and understand...’, in which the following steps have been taken:

- i. take as point of departure the typology of the Ilhas in terms of houses, streets and blocks as described from the historical perspective;
- ii. take a specific cluster as representative location for of the phenomenon of the Ilhas;
- iii. involve inhabitants by doing participatory research –as a form of urban anthropology-, including interviews and observations of daily practices and community live;
- iv. define relevant scales of spatial analysis based on social and physical relationships for detailed morphological description and analysis;
- v. define the stability of social, physical and economical relationships of the Ilhas;

vi. take this stability as starting point to characterize the Ilhas and to define the actors which could be considered the agents of urban and morphological transformation.

In this way 'assemblage' is considered a procedural and a material concept, referring to formal object (research method) and material object of study: the morphology of the Ilhas.

Selected location

The investigation took place in a selected cluster of Ilhas in the central area of Porto. The São Victor street cluster was chosen because of its large size, and also due to its authentic character, where the Ilhas still kept their original form (Figure 7).

Figure 7. Location of São Victor street in the city of Porto.

The area of São Víctor street is located within Bonfim neighbourhood, and can be seen as a buffer zone. On the left side of São Víctor street, the city is lively and crowded, with the Old Town and the Centre of the city, with main touristic attractions and commercial areas. But towards the eastern side, a large cemetery followed by the railway form a whole different environment, already outside the main city route. São Víctor street is located in between, forming a transitional space. The privileged location in the city is indeed one of the strongest characteristics of São Víctor street. The Street is located on the eastern side of Porto, nearly to the City centre. The street is short (625 m long) and the Ilhas can be found only within a part of its length (367 m, between Praça da Alegria and Largo do Padre Baltasar Guedes). The street ends at a cliff, with a great view to the railway and the Douro River.

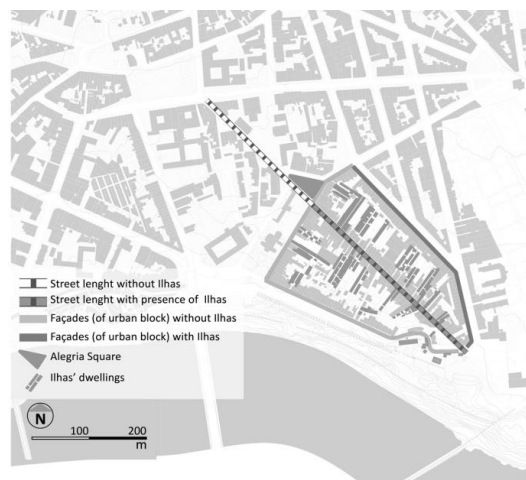

Figure 8. The Ilhas of São Víctor street.

The study area (Figure 8), formed by the group of urban blocks on both sides of São Víctor street, has a total of 1.388 inhabitants (data from the Census 2011 – INE, 2012). In an estimation based on observation combines with the aerial photos of the area, it can be assumed that the 29 Ilhas contain 280 dwellings. Given that the average household size of 2.6 people (data from the Census 2011, INE, 2012), the estimation results in around 730 people, from the total of 1.388 people in the study area, living in these Ilhas.

Some of the Ilhas are empty, but the majority is at least partially occupied. Their pattern follows the original Ilha typology, with small houses occupying the backyard of larger houses, connected to the street through a long corridor. Given that there is no official data concerning the Ilhas' dwellings, these conclusions come from a combination of aerial photos analysis and visits to the area.

Participatory research

The participatory research took place during field visits. The selected location was visited and observations of the public space were made in different time frames and different days of the week. During this visits, interviews with the inhabitants were made following an non-structured interview approach. They took place like informal conversations, when the inhabitants usually felt more confident to talk, without fearing that it could be an official interview from the Municipality (although some of them fearfully asked if it was a Municipal initiative). Besides interviewing inhabitants, other people involved in the subject were also interviewed.

The impressions

Despite the lack of living quality conditions, the inhabitants show an impressive level of satisfaction. Having some interesting conversations is not a difficult task on São Víctor street. Especially the elderly are quite sympathetic. They enjoy sharing their stories and their love for their living space. The most heard sentences in São Víctor Street are: "I will die here" and "I would never leave this place". The impression is that the value of the neighbourhood and its community is still lively present in São Víctor. The community is the first item mentioned in a description of positive aspects of the Ilha life. People know each other, families grew up together. There is a feeling of cooperation, company and friendship, which is strong especially for the elderly. They have been there for a longer period of time, and have tighter relations with the space and with the others. They also keep company to one another, since they are in many cases alone.

Furthermore, the high social control of the street provides safety, and the fact that the people know each other and see each other constantly is an obstacle for criminality. The high density added to the strong contact to the street only increases the general sense of security.

The dwellings surely need improvement in several aspects, but their environment is a success concerning one of the most important aspects for the inhabitants: the satisfaction of living where they live, and the sense of belonging to a place. Each Ilha is unique as a place. They have different stories and different names. Their names are sometimes quite out of the ordinary. They were named after a former landlord, a famous inhabitant, or a characteristic of the Ilha itself. The names give to the Ilhas a sense of identity and place.

The Ilhas of São Víctor street are a place for numerous problems, but they also have several positive aspects. The Ilhas have always been seen, either by the authorities or by the population, as a shameful city problem that needs to be vanished. The change of times ask for a change of point of view. The Ilhas should be faced and analyzed from a different point of view, associated to the current time of (deep) economic, social and political crisis.

Thus, positive aspects should certainly be equally considered.

Morphology and typology analysis – scales of space

Because the social environment forms the greatest positive aspect of the life in the Ilhas, the social relationships will be used as the main criteria for classifying and separating the different scales of space during the morphological analysis. From the most public to the most private space (Figure 9), the pattern of social encounters and the relationship between users and their space defines invisible boundaries within the urban environment which create different 'heterotopias'.

Figure 9. The impression on entering an Ilha.

From public to private

The group of social acquaintances from a person reduces gradually, from the most public space until the privacy of the household (Figure 10). The public space is opened for everyone, and a stranger would not be easily noticed in this scale. The collective space is more narrow, where the community formed by all Ilhas is able to meet, and a stranger who does not belong to the street is already perceived and observed by the users of the space. The communal space is the rather special scale of the Ilha corridor. Its level of privacy may vary according to the type of entrance of the Ilha, but the corridor is mostly more private than public. Finally, the household space provides privacy and protection to the resident.

Applying these scale division to São Vítor street and the Ilhas, the result is a hierarchy of three layers of space, divided according to the scales of privacy and level of social contact. The household space is not included. The main difference between these scales of 'publicness' of the spaces concerns who meets in the space, and which social relationships take place in them.

Figure 10. The social relationships defining the spatial scales.

Large Scale - The public space outside

This scale represents the room for social relationships between the residents of Ilhas and outsiders, which take place in the public space in the surroundings of the street. These spaces form the boundaries of the urban blocks where the Ilhas are located. These boundaries work as a type of barrier to the study area, and it represents the conflict between the urban block formed by the Ilhas of São Vítor and the surroundings.

The Ilhas have an embedded bad image within the city, as a result of their historical condition of unhealthy environment. The area forms a buffer zone in the city and does not relate itself to the very next surrounding area. The urban block is an 'island' itself. The challenge in this scale would be to increase the reciprocity between the block and the city, to make the Ilhas part of the larger urban scale.

Medium Scale - The collective space of the street

The collective space is still public – opened for all people. Nevertheless, it is a space already filtered by the first boundaries, forming a different heterotopia. The inner-block space of São Vítor street is mostly used by inhabitants, and a stranger passer-by is already noticed. These collective spaces include the street itself, with its sidewalks, and its adjacent spaces, such as open spaces, commercial buildings and the alley connecting the street to the riverside (and a beautiful view). The collective space is a key for the binding of the whole community, and where people from different Ilhas meet. As mentioned by an elderly lady in an interview: "In the past, this street used to be a large family".

But why 'in the past'? An increasing unsafe feeling and decreasing community status has been mentioned by several inhabitants, especially by the elderly. The amount of newcomers is increasing, as a possible result of the economic crisis and of the demolition of social housing buildings in the suburbs. Newcomers are often held responsible for the neighbourhood changes, because their relationship with the neighbours is not as strong as in the past generations. Thus we can speculate that a generation clash might be a part of the problem. As a result of less social acquaintances, the community status decreases and therefore the social control also becomes weaker. Re-establishing the strong social control from the past through incentivizing the community strength might be part of the solution for the decreasing security and social decay.

Small Scale - The communal space of the corridor

The corridor of each Ilha is already a private space, located within a private urban plot. Nevertheless, due to the use by several families, and in some cases the openness to the outside world, this space can be considered semiprivate, or communal. It is shared by all neighbours within the Ilha, and is also an extension of the household. The inhabitants place outside, in a thin line along their dwelling, several personal belongings which coexist with the neighbours in the narrow corridor. Laundry, plants, chairs, toys, and several other objects give to the corridor a 'private backyard' impression.

The Ilhas slightly vary in their morphologic features (Figure 11), with a variation regarding the level of connection with the street defined by the entrance to the corridor. The extra level of public-private transition provided by the corridor and the reduced size of this common space, makes from the narrow corridor become part of the dwelling. At the same time, it is an extension of the street, keeping the line between private and semi-public rather porous. The corridor of the Ilha is a distinctive space, since it represents the very basis of the community strength from the Ilhas. It gives an extra level of collective privacy to the Ilha, and is partially responsible for increasing the social cohesion, community strength, and is consequently improving the social control.

Figure 11. The degree of privacy defined by the entrance typology.

Concerning the dwellings, their dimensions are mostly very compact. Some of them have an extra pavement which was usually built by the inhabitants. Some families rent more than one dwelling, and make from both one larger house. The façades of the dwellings are painted in different colours, and some are covered by tiles. The differences between dwellings of a common Ilha show that the changes had been made by each inhabitant, and not by the landlord. Self-improvement can be found everywhere.

The strength of self-improvement

The Ilhas carry quite a heavy and dark image with their name. They bring an image of insalubrious places, of extreme poverty, justified by their historical existence as an urban problem. Even though Ilhas without sewage and dwellings without private toilets still exist, the situation improved, mostly as a result of efforts from the residents themselves.

Several Ilhas are equipped with private toilets and small extensions for the dwellings, resulting in more life quality for the inhabitants. The residents are usually proud of their accomplishments improving their houses. Mrs. Rosa, from nº 76, declared: “I have my own toilet and a second floor with bedrooms which I built up myself. The landlord does not do anything to improve the houses, everything has to come from us. If your roof is broken, if you want to paint the house, we do it all by ourselves”.

Mrs. Filomena, from the same Ilha, had the best house of all visited ones. Her home is an example of the self-improvement made by the inhabitants. Her family extended the dwelling, using a small space on the side of the house, where was previously an open area.

Now, her son has his own bedroom. Furthermore, they also built an extra pavement, where her bedroom is located, and a bathroom for the family. The house is well maintained, and she mentions: “We pay such a cheap rent that we can afford reforms, and we feel happy to improve our home”.

The differences between the building condition within the Ilhas are quite strong and visible (Figure 12). Based on some interviews, it can be concluded that the improved houses belong to the long term inhabitants, who reformed their space through the years, maybe even through generations. The houses without toilets and with the worst structural problems seem to have a more dynamic occupation pattern, with less permanency of residents. Many of them are now rented by people who arrived a few years ago, and have no funds for repairing the house. The main complaint from unsatisfied residents in Ilhas is related to the low quality of their

dwellings. If the quality is improved, the satisfaction levels rises, the attachment to the space gets stronger and consequently the level of residents permanency in the area also grows. It is a cycle of positive consequences.

Figure 12. Above, a dwelling improved by the residents own efforts; below, a dwelling that show signs of degradation.

Proposal – the self-improvement urbanism

The improvements made by the inhabitants themselves in their dwellings could be the reason that makes the Ilhas a resilient urban space. A better living environment plays a role in the satisfaction of inhabitants and permanency in the living space. As these effects have a strong influence on the great community standard of the Ilhas.

The extension of this practice to another dwellings – the ones which still need improvement – could be an inexpensive way of improving the qualities of such houses. The advantage for the landlord is the improvement of his property without any effort or investment coming from his side. The residents would work by themselves, as they have been doing for generations of small self-improvement, but this time in a greater scale. The advantage for the inhabitants is the possibility of improving their dwellings and rising their living quality standards. Furthermore, the group approach would boost the community integration and help solving the increasing social decay.

Mrs. Ineke Hulshof, from the office Hulshof Architecten, has several examples of successfully realized residential buildings developed under the concept of cooperative construction. During an interview in June 2012, Mrs. Hulshof was quite optimistic when asked about a possibility of cooperative building in the scenario of the Ilhas: “I believe that the people can do it themselves. There is always someone that knows how to build or knows how to fix a roof or a toilet, and they can teach each other. If well organized, they can surely do it” (Hulshof, 2012).

The self-improvement concept could go beyond the dwelling and reach the urban scale (Figure 13). The community is strong, and could be used as a basis for the urban transformation where the inhabitants themselves are the agents of change. Since it has never been an intention from the authorities of Porto on rehabilitating the Ilhas, but only to demolish them, an improvement plan for the Ilhas should not rely on tools like legislation support, and much less on public investment. In times of economic and political crisis, the interest in investing, coming

from the Municipality, became even less significant. Therefore, the methodology for such transformation should be planned with little or no governmental support.

Figure 13. The self-improvement urbanism applied on the study area.

The urban issues identified in the scale analysis could be approached in the same method of self-improvement. In the large scale, the reciprocity between São Vítor street and its surrounding area can be increased through the enhancement of the use of the available public spaces by both social groups (residents and outsiders). Movable urban furniture have low costs and maintenance, and could be implemented by the community itself in strategic public spaces where the connection can be made with outside users for a more intense use of the space. The augment of connection between these groups would diminish the isolation of the Ilhas area and, in a longer term, would also diminish the negative image that the space has in the city.

In the medium scale, the collective space of the street provides room that could be used for the community incentives and connection between the older and younger generations. A great community incentive might be reuse available space, transforming it into common space that facilitate social encounters. Since their dwelling space is so small, extra facilities could be offered as an extension of their houses, just as the corridor space works. A shared outdoor laundry space or a community urban farm are possible ideas. The opinion of some residents was asked during some of the interviews. The idea of a shared cultivating area or space to grow chicken had positive reactions. People especially enjoyed the fact of producing their own vegetables and eggs and also spending an enjoyable time outside. Such simple activities could be implemented and maintained by the community itself.

Conclusion

Despite the low quality living conditions, the inhabitants of the 'Ilhas' show an impressive attachment to their living space, forming a strong community. This quality could be used as

foundation for the ‘self-improvement’ urbanism, where the community operates as the main engine of the urban transformation.

The main finding of the research is that the ‘Ilhas’ could be an inexpensive solution for the current housing crisis through the further development of the ‘self-improvement’ urbanism. This innovative approach includes strong public participation and an innovative position of the planner within the process.

The 'ilhas' of Oporto, a fundamental component of the city's nineteenth century urban morphology

Manuel Teixeira

CIAUD – Centro de Investigação em Arquitectura, Urbanismo e Design, Faculdade de Arquitectura, Universidade de Lisboa. E-mail: manuelteixeira@gmail.com

Abstract. *The 'ilhas' are nuclei of working-class housing that were built on Oporto in the second half of the nineteenth century, in the period of greater industrial development of the city. The 'ilhas' were made up of groups of small houses, with an area of about 16 square metres, built along the back-gardens of middle-class houses (or which had been originally built as middle-class houses) in areas of the city that, given their proximity to industries located nearby, had begun a process of physical and social decay that would be further accentuated by the construction of these working-class houses. These houses were built either in a row, along the 5.5 or 6 metres wide urban lots, or in two rows, back-to-back or facing each other, when they occupied two of these plots. They were not unlike similar forms of working-class housing built elsewhere in Europe in the same period, and they would be replicated, by Portuguese emigrants, later on, in Brazil. Small areas, bad construction and a lack of the most basic infrastructures were translated into deplorable housing and sanitary conditions, endemic illnesses and high rates of mortality. Towards the end of the nineteenth century, it is estimated that between one-third and one-half of the population of Porto lived in these conditions. Despite these numbers, and the sheer presence of their inhabitants in urban life, most 'ilhas' were invisible from the formal city: built in the back-gardens, in the interior of urban blocks, their sole relationship with the street was by means of a door – no different from any door – on the façade of the middle-class building facing the street, that led to a corridor under this house and next to an open corridor along the back garden where the rows of small houses were built. In the existing city's cartography they were also absent. Their presence would only be acknowledged towards the end of the century, when a number of epidemics, and a new cartographic survey of the city, led to their formal recognition on the part of the bourgeoisie and the municipal authorities.*

Key Words: 'Ilhas', working-class housing, Oporto, nineteenth-century, industrial city.

General context of development of 'ilhas'

The 'ilhas' are a form of working-class housing which developed in nineteenth century Oporto. This kind of housing consisted of rows of small houses, built in the back-gardens of middle-class properties and with access to the street only through narrow corridors under the houses which faced on to the street.

With the advent of industrialization, and the consequent immigration into the city, the two main solutions to house the lower income groups were, first, to increase the density of existing buildings in the old neighbourhoods up to a saturation point and, second, the development of new speculative housing in the form of 'ilhas'. This later kind of housing consisted of rows of small houses, built in the back gardens of middle class properties and with access to the street only through narrow corridors under the houses which faced onto the street. Subsequent developments made this house form independent of the middle class housing and, in some cases, spread this typology into whole areas of the city, which became exclusive working class wards.

The first immigrants into the city were mostly young, unmarried men who could not find the necessary means of subsistence in the countryside, and salaried rural workers, and even small property owners, who were obliged to procure work in the city in order to survive. Initially, these men retained a link with the land, where their families remained looking after their plots

of land, and where they returned every weekend. During the week, they lived in lodging houses, in the old neighbourhoods of the city. This accounts for the high housing densities registered in the central parishes of the city – Sé, S. Nicolau, Victoria and Miragaia – according to the first census of population in 1864.

By 1881 just over one third of the population of Oporto was dependent on the industrial sector; nine years later, in 1890, that proportion had risen to nearly half of the total population of the city. Correspondingly, the years between 1864 and 1900 are a period of great increase of population in the city, most of it due to immigration from the countryside. Throughout this period the population in the central parishes of the city remained stable, and this new population became established in the outer parishes of Bonfim, Campanhã, S. Ildefonso, Cedofeita and Massarelos, where most 'ilhas' were built in this period. Thus, the housing of the workers in the overcrowded buildings in the old neighbourhoods and in the 'ilhas' corresponded not only to different periods of migration into the city but also to a different type of migrant; people living in the 'ilhas' being a much more stable, family-based population. The 'ilhas' soon became the dominant type of workers' housing in Oporto, and until the 1930's virtually the only way in which new working-class housing was produced. By the end of the century it was estimated that nearly one third of the population of the city – 168,000 inhabitants in 1900 – lived in 'ilhas'. According to a survey carried out in 1899 there were 1,048 'ilhas' with 11,129 houses and lodging 50,000 people (Teixeira, 1994).

Therefore, the 'ilhas' arose as a consequence of the industrial development of Oporto in the second half of the nineteenth century. That is evidenced by their dates of construction, after the 1860's, subsequently to the complete overcrowding of the old neighbourhoods, and coinciding with a period of great immigration into the city, their predominant location near the main industrial areas, and the social composition of their inhabitants, mainly workers.

The 'ilhas' were the result of a secondary process of urbanization, most times superimposed on older middle-class urban developments. The stage of development that is specific of the 'ilhas' is their construction, since the division of land and urbanization of areas of the city where 'ilhas' were built had taken place years and decades before, when the areas concerned were developed as middle-class neighbourhoods.

The 'ilhas' were built at the margin of Municipal by-laws concerning the building of housing. These by-laws were applied only to the constructions that were built facing on to the street; the 'ilhas', because they were built inside the blocks, escaped from their control. The attitude of the Municipality would be characterized till the end of the nineteenth century by a complete disregard concerning both its development and the serious problems that soon surrounded the existence of 'ilhas'. For the successive Municipal Administrations in nineteenth century Oporto, the bourgeois city was the only existing reality. The 'ilhas' were regarded as something exterior to that apparent reality, and therefore not considered or even mentioned in the Municipal policies formulated by successive Administrations. It was only after the epidemics of bubonic plague in 1899, which had its main focus in areas of 'ilhas' and subsequently spread to other areas of the city, that the Municipality took the first legislative and sanitary measures regarding working-class housing.

Built predominantly within the blocks of middle-class housing, these nuclei of working-class housing do not participate in the surrounding urban structure. The only communication of the 'ilhas' with the street was through a narrow tunnel corridor under the middle-class house facing on to the street. Quite often, the entry to this corridor was concealed behind a door included in the composition of the façade. In Oporto, the spatial segregation of working-class housing was not made through their location in different areas of the city. With a few exceptions of working-class wards in the Eastern part of the city, that segregation was made in terms of exterior and interior of the blocks: on the exterior, middle-class housing facing on to the street, the visible face of the city; on the interior, working-class housing built within the blocks, and invisible from the street. This physical "invisibility" of workers' housing had its translation, at the institutional level, in the disregard of the Council towards the construction and the existence of 'ilhas'.

The development of 'ilhas' took place outside the usual circuits of property and building promotion and by social classes other than those usually involved in such activities. The landed bourgeoisie of Oporto, who controlled the urban development of the city in the nineteenth century, was engaged essentially in land promotion for the middle-classes, and it did not invest in the construction of working-class housing. The construction of 'ilhas' was the result of the investment of small capitals on the part of the merchant petty bourgeoisie which had in the 'ilhas' a privileged field of investment for their small savings: a small initial investment and the certainty, assured by the great demand for this type of housing, of the rapid amortization of the capital invested and the obtainment of profits in a short time.

In this sense, the 'ilhas' are the result of processes originated in a subeconomy of small capitals of commercial origin. The holding of land in Oporto was subdivided in a chain of successive leaseings, and the provision of housing for the workers was left to those further down in the landholding hierarchy, to the lessees and sublessees of single plots of land. Working-class housing in Oporto was characterized by its fragmented character. It was the result of multiple small initiatives scattered all over the city, which found their formal expression in the 'ilhas'. The intense use of the land, the low building costs, and virtually no costs of infrastructures, ensured the maximum profitability of the capital invested and made the construction of 'ilhas' a field of investment open to small capitals.

Thus, the 'ilhas' were the result of marginal processes of housing promotion in the nineteenth century, but they were also the result of processes of marginalization concerning bourgeois housing areas in the city. In certain bourgeois areas of the city built in the first half of the nineteenth century, the ageing of these neighbourhoods, the encroachment of industries or working-class housing nearby, or the development of new bourgeois neighbourhoods in other parts of the city, led to a decline in the demand for middle-class housing in such locations. This process, which occurred in the second half of the nineteenth century corresponded to the marginalization of such older bourgeois housing areas, and created favourable conditions for the development of 'ilhas'. In fact, 'ilhas' were built predominantly in former bourgeois housing areas which, as a result of processes of functional transformation in the city, were marginalized by the class that initially inhabited them.

Spatial conditions

One of the main characteristics of the 'ilhas' is their construction within the urban fabric built in the late eighteenth century. This inward growth of the city, embodied by the 'ilhas' is one of the most important aspects of the spatial development of Oporto in the nineteenth century.

In the late eighteenth century the Governors of Oporto planned and carried out a series of public works aimed at the definition of the main lines of future development of the city. The main objectives of the Almadás – father and son, Governors of the city from 1757 till 1804 – were threefold: the construction of new residential areas for the rich merchant bourgeoisie outside the medieval nucleus, the establishment of new and better communications between the active business centre by the river and these new neighbourhoods, and the definition of new lines of expansion for the city. Four major axes of development, which would support future urban growth, were built. Together with the transversals that connected them, they defined the basic urban structure of the city beyond the old city walls.

The plans for these new urban developments, promoted by the "Junta de Obras Publicas", included joint elevations, sometimes corresponding to long street fronts, to which building promoters had to subject their own projects. Such plans were carefully designed taking into account the existing irregular parcelling of the land, and the dimensions of the different lots. In other cases, because land had been expropriated, the land parcelling was reorganized: its basis was a land parcel 25 "palmos" (5.5 metres) wide and usually very long, up to 100 metres. This narrow urban lot would be adopted in most new nineteenth century urban developments. In

addition to the curtailment of infrastructures' costs, this lot dimensions increased the number of possible constructions in a given street front.

The individual lot became in the nineteenth century the fundamental unit in the development of the city, giving free enterprise the greatest flexibility of intervention. Different parcels could be developed separately, by different people and at different times, with different typological characteristics, taking into account only the speculative interests of their owners and the market conditions. The regularity of the urban lots was at the same time the consequence and the logic pattern for the _capitalistic development of the city. Their regularity made all planning operations extremely simple, thanks to the simple multiplication or division of costs, prices and profits by the number of possible lots in a given piece of land. Land had become a commodity, and the development of the city subjected to market laws. On the other hand, this lot width. had a technical justification, based on the technology of construction at the time: this width corresponded to the maximum span of a wooden beam supported on the load bearing walls built at both extremes of the lot. The development of architectural models based on such dimensions, which master builders learned to build and repeated all over the city, contributed to the spreading of this urban typology.

The regular parcelling of urban land in lots with 5.5 or sometimes 6 metres of front width, or their multiples for bigger buildings, had direct consequences on the development of the 'ilhas'. This parcelling of the land was at the origin of the typological characteristics of this form of housing. In its simplest form, an 'ilha' consisted of rows of houses built along these narrow lots: in a single row when built in a single lot, in or in two rows when built in two lots. From these, other, more elaborate variants would evolve. Most times the 'ilhas' were built inside the blocks, occupying the back-gardens of middle-class houses. In some other cases, the 'ilhas' would occupy whole lots, coming up to the street.

The expectations of the Almadás as regards the urban growth of Oporto were not matched by reality, and in between the major axes of development built by the "Junta de Obras Públicas", large extensions of land remained empty till late in the nineteenth century. In certain locations, such areas were occupied by working-class housing. Sometimes superimposed on old rural structures, the development of 'ilhas' gave these areas a predominant working-class character, not mixed with middle-class housing developments. In such cases, although free from the limitations of lot sizes, it was still the typologies of 'ilhas' that were adopted.

Most 'ilhas' are located in an arch surrounding the old nucleus of the city within the eighteenth century extensions of the city. Greater concentrations of 'ilhas' were built near the main industrial areas: to the East, in Bonfim and Campanhã; to the West, in the areas of Lordelo and Massarelos; and to the North the nucleus of 'ilhas' of Bouça, Lapa, Leal and D. Joao IV. By the end of the century it was estimated that nearly one third of the population of the city – 168,000 inhabitants in 1900 – lived in 'ilhas'.

Stages of the process and social actors involved

The great development of private construction in the city took place since the middle of the 1870's, following an increase of Municipal works. The opening of new streets and new building fronts stimulated house building through private initiative. In the fourteen years between 1864 and 1878, 2,700 buildings were built or rebuilt in Oporto, according to plans approved by the Council. Nevertheless, these 2,700 new construction were not enough to house the growth of population registered in those years - 19,000 inhabitants from 1864 to 1878. Even considering that those buildings might house 10,000 new inhabitants (which is an excessive number, since 40% of these works were extensions of existing buildings or reconstructions), there was still a surplus of 9,000 inhabitants, whose only destiny was the overcrowding of existing houses, or the 'ilhas'. The construction of 'ilhas', given that they were not subjected to Municipal approval, are not included in these numbers. On the other hand, the old and overcrowded

districts of the city registered in this period extremely low population - increases, and consequently the housing of these 9,000 inhabitants had to be found in the 'ilhas'.

The 'ilhas' began to be built in large numbers from the middle of the 1860's onwards. Between 1878 and 1890 the number of constructions in the city was about 4,700; to them corresponded the housing of 19,000 inhabitants. Since the growth of population in Oporto in this twelve year period was about 33,000 inhabitants, that means that 14,000 people were left homeless. Also in this case, this population found their housing in the 'ilhas'. Finally, between 1890 and 1900 the number of constructions municipally approved was 2,700. It is noticeable here a decrease in the rhythm of construction, owed in a large extent to the grave financial crisis that affected Portugal since 1891, with serious reflexes in the city of Oporto. To these 2,700 constructions corresponded the lodging of 11,000 people, leaving another 18 000 people without accommodation, considering that between 1890 and 1900 the population of the city grew by 29,000 inhabitants. In short, from 1864 till 1900 about 41,000 new inhabitants in the city had to find accommodation outside the houses that in this period were built with the Council approval. We believe that most of these 41,000 people found housing in the 'ilhas', the construction of which is not reported in Municipal statistics (Teixeira, 1996).

There was a sharp increase in the number of 'ilhas' after 1878. In the short 12-year period between 1878 and 1890 about half of the houses in 'ilhas' were built, whereas their construction declined after 1890. Nevertheless, the development of industry and the continuing immigration into the city, although at a slower pace, continued to ensure a strong demand for working class housing. The insufficient responses of the Municipality and the Government regarding the construction of State sponsored worker's housing, meant that, according to a new survey carried out in 1939, there were then in Oporto 1,152 'ilhas' with 13,000 houses and 45,290 inhabitants (Teixeira, 1992).

Despite the growth of industrial production from 1835 onwards, the industrialists would never become the dominant social class in the city. The merchant bourgeoisie was the dominant social and economic class in the city. It was this class of property owners who were in control of the development of the city throughout the nineteenth century. When not the owners of the land in full ownership, they were the lessees of great estates.

This landed bourgeoisie was, by the middle of the century, mostly engaged in speculative activities; besides the speculation on land, their investments were mostly in shareholding. In no way did they constitute an entrepreneurial class. Theirs was a parasitic capitalism of rent collection, usury and stock exchange speculation, mostly in government bonds and shares from public works' companies backed by the State. Their names are never found related to any industrial enterprise, and in the same way they would never assume the risk, or indeed the trouble, of building for the workers.

Despite the great increases of population in the city in the second half of the century – 81,000 inhabitants between 1864 and 1900, nearly a 100 per cent increase – and the urgent need to house such masses of people, the landed bourgeoisie who had in their hands the mechanisms of development of the city did not answer this challenge and, with very few exceptions, did not invest in building for the working classes. The reasons for this have to be found both in the characteristics of this bourgeoisie, and in the structure of the industrial sector.

The low wages paid to the workers gave them access only to the most poor kind of housing. The allocation of land and the provision of housing purposely built for the working classes would raise the rents to levels not affordable by the workers. Therefore, it was not just a question of the lack of enterprising capacity of the bourgeoisie involved in property development, but also a problem of the industrial bourgeoisie, which had in the low wages paid to the workers one of the main conditions for its survival.

Landed properties in Oporto were leased for three lives – the lessee, the spouse or the husband, and one descendant – after which the lease was renewed and a new rent established. The lessees, in turn, although subjected to conditions imposed by the original landowners, were free to divide the leased property in lots and sublease these parcels, collecting rents that taken together far exceeded the rent they paid to their lessor. The property in Oporto was thus

subdivided in a chain of successive leasings, and its ownership hierarchically organized: the direct landowners, the lessees, and the sublessees.

The lessees of individual plots of land in the city were for the most part middle-class people, merchants, traders, shopkeepers, sometimes craftsmen, who rented those lots to build their own houses. If one excepts the building of 'ilhas', most cases of building promotion were for owner occupancy. Certain locations in the city were preferred by the upper middle-classes, while in other locations the petty bourgeoisie and a certain working-class aristocracy of independent artisans could be found mixed.

The reform of the civil code in 1697, transforming the renewing leases into perpetual leases, gave rise to changes in the controlling mechanisms of this system, and the original landowners progressively lost their control over their properties and their development. Because the rents could not be increased, the depreciation of currency made old rents turn into insignificant values, and the whole system collapsed. As a result of that, the actual property of the land passed on to the tenants. This process would favour the development of 'ilhas'.

With the exception of very rare situations, no 'ilhas' were located in any of the main streets that were opened up in the city after 1865. In those areas of the city, which developed in the 1870's and the 1880's, the ownership of land was still concentrated in the hands of the land promoter, who was able to impose conditions on the use of the land and prevent the building of 'ilhas', which would have given rise to a fall in property values. Also, the prices of land in these new, fashionable streets were high, and therefore not compatible with the economics of working-class housing.

On the contrary, in the areas of the city that had been built in the first half of the century, the land had already been divided in numerous small lots and leased to different individuals. As the years went by, the control by original landowners over the development of those areas had become rather weak. Because of the changes introduced by the new civil code in 1867, that control had become virtually inexistent at the time of great demand for working-class housing. In these circumstances – property divided, with many landholders, lack of control over the use of the land on the part of direct landowners, aged areas, depreciated by industrial developments located in the vicinity, the development of new fashionable residential areas for the wealthy bourgeoisie elsewhere in the city, and great demand for working-class housing – conditions were created for the development of 'ilhas' in such older urban areas. Sometimes, these two phases – middle-class house building and working-class house building – were separated by years and decades; some other times, they were almost simultaneous, and the areas concerned were never fully developed as middle-class housing areas.

The builders of 'ilhas' were many times the original owner-occupiers of middle-class houses, who built 'ilhas' in their own back-garden. In other cases, the original occupier would move out, and the property was sold to someone else with enough capital to build an 'ilha'. Most builders and owners of 'ilhas' were simple tradesmen or craftsmen to whom the 'ilhas' represented a safe and profitable investment for their savings. The small scale of the enterprise, and the little investment they represented, made the 'ilhas' – the object of the speculative activity of a large sector of the middle-classes in nineteenth century Oporto. On the other hand, the profitability of the investment was very high; in certain 'ilhas', the annual rents collected from all the houses represented 25% of the market value of the 'ilha', that is to say, the capital invested in their construction would be fully amortized in four years' time. In most cases that period was about ten years. As a result of that, men of higher financial means, not usually involved in the construction of 'ilhas' started to promote working-class housing as well. They were successful traders, rich migrants returning from Brazil, and in some cases even a few landowners involved themselves in the construction of 'ilhas'. They would buy or lease plots of land and promote the construction of 'ilhas', some of them becoming the owners of numerous 'ilhas' in different parts of the city. In these cases, the 'ilhas' were generally bigger and had much better housing standards than the average. Because of the higher investment necessary to build such 'ilhas' their promoters resorted to bank loans for their construction. However, either because of bad management, or because the costs of building better quality working-class housing were

incompatible with the economic capacity of the workers and their ability to pay higher rents, such enterprises generally ended in failure.

Location and morphologies of 'ilhas'

Most 'ilhas' were located in the parishes of S. Ildefonso, Bonfim, Campanhã, Paranhos and Cedofeita, which surround the old nucleus of the city to the North and the East. Together, these parishes accounted for 75% of the 'ilhas' in Oporto. The parishes of Massarelos, Lordelo and Paranhos, to the West, had another 14% of the 'ilhas'. These were the parishes that registered bigger population increases between 1878 and 1890, when most 'ilhas' were built. Bonfim, Campanhã, S. Ildefonso, Cedofeita and Massarelos, alone, registered population increases in this period of about 2/3 of the total growth of the city. The four parishes in the historical centre of the city – Sé, Vitoria, S. Nicolau and Miragaia – accounted for only 7% of the 'ilhas'. The remaining 4% were located in the outermost parishes of Aldoar, Nevogilde and Foz, away from the main industrial locations.

As regards their typologies, most 'ilhas' were built inside the blocks, either isolated or in clusters. At the origin of the typologies of 'ilhas' was the general adoption in nineteenth century urban developments of urban lots with a front width of 5.5 or 6 metres. The simplest type of 'ilha' consisted of a row of small one-storey houses built side by side and all along one of these parcels, which were sometimes up to 100 metres long. All the houses opened onto a narrow corridor running all along them, with a width usually not exceeding 1.5 or 2 metres, sometimes decreasing to just one metre, the strictly necessary to give way to the inhabitants. In 60% of the cases, these passageways had less than three metres of width. In other cases, the 'ilha' was built in two lots. Here, the houses were located on both sides of the parcel, opening to a central path, common to both rows of houses. The joining of two lots allowed greater areas for access corridors, sometimes up to 4 metres wide. In either of these cases, houses had only one free frontage. Their rears were propped up against the enclosure wall of the lot or the backs of another row of houses of the 'ilha' built on the neighbouring lot. Sometimes, when the 'ilha' was built on two parcels of land, the two rows of houses were built back-to-back in the middle of the plot, leaving two lateral corridors for access.

These were the two basic typologies of 'ilhas', which were developed from the 6-metres wide urban lot. The development of these typologies, and the related housing typologies, led to their adoption to situations where those limitations of lot dimensions did not exist. They were the most rational typological solutions in terms of intensive use of the land, curtailment of construction costs, and consequently of economic efficiency. When working-class housing was built on larger pieces of land, the most usual solution was still the construction of successive rows of houses built back-to-back, using the typologies and dimensions of smaller 'ilhas'.

'Ilhas' varied a lot in their sizes. Small 'ilhas', consisting of up to twenty houses, were the majority in Oporto; sometimes they had as few as four or five houses. The biggest 'ilhas' could have 100 or more houses, and because they represented bigger enterprises and higher investments, they usually had better housing standards than most smaller 'ilhas'.

The relation between the 'ilha' and the street could take different forms. When there was a middle-class house facing the street, and occupying the whole front of the lot, the access to the 'ilha' built in the rear was made through a narrow tunnel corridor. Under this building. This house looking on to the street was usually a bourgeois multi-storey house, sometimes the dwelling of the owner of the 'ilha' himself. In other cases, the 'ilha' had a free communication with the street, through an open passageway next to the front building. This building did not occupy the whole front of the lot, leaving a narrow passage, which in most cases did not exceed one metre, for access to the 'ilha'. The existence of this open passage means that the front house and the 'ilha' were built at the same time.

The 'ilha' could also occupy a whole parcel of land, coming up to the street, without any middle-class building in front of it. The most usual solution in these cases was the construction

in two lots, with two rows of houses opening to a central path. The street frontage was made up of a simple wall, in which a door to the 'ilha' was opened. Sometimes, later on, the first house in the 'ilha' opened windows in this wall giving on to the street. In some more elaborate examples the 'ilha' itself built a façade to the street: making the first houses face the street, signaling its entry, or giving a name to the 'ilha', the last phase of its affirmation as a recognizable housing form.

As regards equipment and infrastructures, they were very poor. In most 'ilhas' there was no sewage system or water supply. According to a survey of 'ilhas' carried out in 1933, at this late date only 7% of the 'ilhas' were connected to the urban sewage system. All the others used cesspools. This situation was certainly even worse in the nineteenth century, before the construction, in 1905, of the new sewer system in the city. The lavatories were common to all inhabitants of the 'ilha'. According to that survey, there was on average one lavatory for every 5 houses or 25 inhabitants. Domiciliary supply of water, although established in the city in 1882¹, did not exist in the 'ilhas'. Water was provided by public fountains or, in some cases, by a well, but the nearby location of cesspools made the water unsuitable for consumption. Open spaces were usually very small, in most cases reduced to the narrow access corridor to the houses. Nevertheless, although rare, there were examples of 'ilhas' where there was room for a small vegetable garden.

Concerning the typologies of houses, their areas rarely exceeded sixteen square metres, decreasing in some cases to just nine square metres. In the most common type of such houses, its front was 4 metres wide, with only one door and one window. Its depth was also 4 metres. With just one storey and an area of 16 square metres, they consisted of a living room, a small sleeping-room or alcove, and a kitchen. Their dimensions were the following: the living-room 4x2.5 metres; the alcove 2.5x1.5 metres; and the kitchen, against the back wall, 1.5x1.5 metres. Houses with more than these three divisions were rare. Because the sleeping-room was very small, the living-room was also used for sleeping. In some cases, a small room was improvised in the attic, to which a narrow and steep staircase led. The ceiling of the houses was the bare framework of the roof, external walls were generally made of stone, and the internal partitions of wood. These partitions were not complete, because they did not reach the ceiling.

The houses were low, their high varying from two metres at their lowest point till 2.5 metres at the ridge. As a result of that, sometimes the total volume of the house did not reach 30 cubic metres. The situation worsened by the absence of cross ventilation. Also, the windows were very small in relation to the space they were supposed to illuminate; because every house had just one small window, in some cases illumination was increased by means of glass tiles. Construction was very poor and a few years after construction, in the damp climate of Oporto, these houses were rapidly decaying.

Some 'ilhas', and houses in 'ilhas', had much better standards. In such cases internal streets were wider, and communal spaces were provided, with tanks for washing. House areas in such cases could be as large as 90 square metres. In most cases the houses were two-storey high, with each dwelling occupying both storeys. Usually 'ilhas' with better standards were amongst the biggest 'ilhas' in Oporto, with 100 to 150 houses, and their construction had been the initiative of the owner of the land himself. However, these 'ilhas' were quite often economic failures for their promoters, unable to pay the debts contracted for their construction. Sometimes, as a means of reducing house rents and making them accessible to most workers, the two-storey houses were split up in two independent dwellings. The result was an increase of densities, and a lowering of the initially better housing standards.

Conclusion

The low initial investment, and the perspective of easy and quick profits on the part of their promoters, resulted in the construction of dwellings with extremely low housing standards, which decayed rapidly. Throughout the years the 'ilhas' were subjected to a progressive decay.

On the other hand, the same conditions that gave origin to the development of 'ilhas' outside the usual circuits of property development, and the usual social strata involved in such activities, were on the basis of the persistence of this housing form in the twentieth century. The dynamics of economic development of the city and the capitalistic mechanisms of transformation of the city were never strong enough to absorb these obsolete land use forms, which became nodules in the urban fabric, hindering its development and sometimes the application of planning directives of the Council itself. From a non-entity in the nineteenth century, the 'ilhas' were, from the early nineteenth century, regarded by the Municipality as a cancer that was necessary to eradicate. Either way, the 'ilhas' were regarded as something external to the bourgeois idea of the city.

Agents of Change

For much of the period of its existence as an identifiable field of academic study, urban morphology has been criticised as being largely descriptive in its approach. This was particularly the case in the formative phase of the 1960s and 1970s when urban geography and social science generally were dominated by quantitative spatial analysis and political economic (mainly Marxian) approaches respectively. Although there may have been some substance to such criticisms they considerably underplay the necessary groundwork in urban morphology that was being established at this time and reflect an assumption that ‘process’ could only be uncovered through the measurement of specific social and economic mechanisms. The priorities in urban morphology were different, reflecting the need to establish a common framework for study including identifying a taxonomy for the analysis of morphological change, the recognition of the key components of urban morphology and methodologies for their examination. Building on this underpinning, urban morphology has subsequently developed strongly in several academic directions but, given the continuing societal, academic and practical interest in change in the physical form of urban areas, much emphasis has been placed on the agents of change. Initially, work focused on the roles played by the principal actors in urban change, particularly land and property owners, politicians, architects, planners and developers. In some ways, this has paralleled the interests of other urban scholars, less concerned with physical form and more with the power relations and economic influences of specific groups in determining outcomes. The ‘Agents of Change’ sessions at the Porto ISUF 2014 Conference will undoubtedly continue to explore some of these relationships, including the examination of the conflicts that inevitably arise between such actors. However, a brief survey of recent literature indicates that the term ‘agents of change’ has moved beyond the consideration of key actors, functioning as individuals and/or groups, and also encompasses the role of institutions, transport infrastructure and connectivity, demographic trends, religion, and street systems. Critics may consider the inclusion of such phenomena to constitute too wide a definition, but their role as factors and processes of urban transformation cannot be denied. The papers to be delivered in the ‘Agents of Change’ sessions promise to explore the role of many of the above in specific situations and stimulate debate on diverse aspects of their operation. Whilst listening to the detailed content of presentations however, it may be useful to reflect on the applicability of specific studies to broader themes and conceptual frameworks. Three such themes will be briefly mentioned here – scale, comparability and the morphological components being studied. The scale of study is vital in its interpretation if only because conclusions drawn at one scale may be considerably less (or possibly more) applicable at a different scale. In any search for concepts of universal applicability it is important to remember the difference that scale makes to empirical reality and theoretical interpretation. Second, comparability of experience, cultures, political systems and many other dimensions remains an important dimension of morphological study and can stimulate some of the most intriguing work. Despite the pressure of globalisation, the question of what sort of processes operate in different cultural milieu remains an extremely important one. Finally, we need to be very clear

which specific morphological components we are discussing and debating, not least because different components change at a very different rate and are themselves subject to rather different processes.

Abstract. *This article aims at understanding the possible influences of public policies on the urban form of fragile and precarious settlements in the city of São Paulo. While establishing the physical, temporal and thematic limits of this study, we chose to analyze housing policies which have been elaborated for the precarious settlement of Heliopolis from 1989 to 2012. Firstly, the paper presents theoretical studies of the housing policy management developed in the chosen period, the founding and building of the slum area, and the main interventions made by the municipal government in the area selected for analysis. Secondly, in the pursuit of comprehending how the different policy guidelines have influenced in Heliopolis, we present an analysis of the Residencial Silvio Bacarelli housing development, a hybrid space created under the influence of different city administrations with distinct guidelines.*

Key Words: *Urban morphology, housing policy management, precarious settlement, Heliopolis, analysis of architectural and urban projects*

Introduction

Scholars of Urban Morphology analyze the evolution of cities from their fundamental principles, considering their constant transformations and identifying their numerous constitutive elements. A city is the accumulation and integration of several individual and collective actions, brought about by cultural traditions and social, political and economic ties over the years. Morphological analyses focus on the tangible results of social-economic actions, by studying the consequences of ideas and intentions on the mutation of urban areas (Antonucci, 2011).

Under this point of view, the research aims at implementing a specific study on the influence of public housing policy management on architectural and urban projects for precarious settlements in the city of São Paulo.

While setting the geographical location and time period for study, the research was delimited to study the influence of different housing policy managements on architectural and urban projects developed for Heliopolis, the second biggest slum area in the city, from the end of the military dictatorship⁷⁷ to today.

Firstly, through a review of the literature, will be outlined the evolution of housing policy management in São Paulo. Considering the aforementioned time period, we will approach the following city administrations: Erundina (1989-92), Maluf (1993-96), Pitta (1997-00), Suplicy (2001-04), Serra (2005-06) and Kassab (2007-12) and present the main housing policy guidelines of each administration.

Secondly, will be outlined the history of Heliopolis. At this stage of the paper, will be recapitulated how the urban fabric of the slum area was formed and how it has changed since its foundation in 1971. Next, a short report of the main constructions proposed by each administration will be presented, complementing the historical analysis and directing it to the paper's topic.

⁷⁷ The military regime began on April 1st, 1964 and ended on March 15th, 1985.

Finally, after the literature review and interview of a São Paulo city servant, will be presented the case study of the housing development on Land H, which was designed by architect Hector Vigliecca and team and suffered influences from two quite distinct housing policies. This is why this housing development was selected for this article.

This article aims to explain how distinct, but clear and well-defined, political guidelines can interfere in different ways in the urban form of a single precarious settlement: Heliopolis.

Theoretical study

In this first part of the paper, this research will be started with the theoretical study with a review of the bibliography. Initially, there will be a brief history of housing policy management in the military government during the Brazilian dictatorship and in the different São Paulo city governments after the reestablishment of democracy. Secondly, will be presented the study on the formation of Heliopolis and the public interventions in the area.

Housing policy management

Historically, housing policy management has been redefined at every change of city administration, which leads to each policy being distinct. The city housing policy guidelines, always influenced by the political foundations which elected each specific administration, underwent transformations and prioritized different objectives, giving way to architectural projects with quite distinct urban characteristics from one another.

Below, there is a review of the housing policy which guided the actions of the military government all over the country, and the municipal policies developed in São Paulo, in the democratic period, when society reconquered the right to direct vote.

Military dictatorship (1964-1985)

From 1932 to 1964, a successful “housing policy” was developed in several states around the country by the IAP’s (*Institutos de Aposentadorias e Pensões* - Institutes for Retirement and Pensions). This phase was marked by the construction of housing developments with internationally acclaimed, high quality, modern architecture.

Between 1964 and 1985, during the Military Dictatorship, housing projects built by public organs and were financially managed by SFH (*Sistema Financeiro da Habitação* - Financial Housing System) / BNH (*Banco Nacional de Habitação* - National Housing Bank) (Antonucci, 2009). Although they were originally built for the low income population, these institutions significantly financed these homes to the middle and high class population. SFH/BNH were effective agents for raising dynamism in the national economy, especially in the housing market, leaving the goal of overcoming the housing deficit only in discourse.

This production was guided by a housing policy that valued the centralization of power, devalued the environment and cultural heritage and prioritized services to the higher income population in order to avoid so-called ‘non repayable’ investment (Bonduki, 2000). This posture gave way to the building of housing developments focused on production and capital investment and not on the quality of the units, neither serving the low income population (Bonduki, 2000). “The housing developments financed by BNH are characterized mostly by their monotonous architecture; absence of connection with the surroundings; locations far from the city center, which extend the city horizontally; their lack of concern with the quality of the projects and physical space, resulting in environmental damage; the negation of the processes of community participation [...]” (Bonduki, 2000: 21).

Sistema Financeiro da Habitação went into crisis after the end of the military dictatorship and the extinction of *Banco Nacional de Habitação* in 1986 ended the production cycle of social interest housing developments.

The Luiza Erundina Administration (1989-1992)

In 1988, with the São Paulo city elections – a few years after the end of the military regime – Luiza Erundina was elected mayor with wide support of the population and the promise to take charge of housing policy management as flagship of her government.

That administration reformed the housing policy, defining new guidelines for projects: decentralized management with emphasis in local power associated to institutions of people's participation, implementation of urban projects to revitalize decadent areas and housing projects in already urbanized areas, self-run collectives and right to land for all.

According to Bonduki (2010), the proposals of that administration were of experimental nature, therefore, they would seek a specific solution for each and every housing problem in the city. There was hope that that experiment would offer references for the formulation of future housing policy management cross-country.

Based on this ideal, they developed projects aiming at the quality of the housing unit with projected and built public space. The space was thought of in public dimensions, beyond the private sphere and with a focus on the low income population (Bonduki, 2008).

The Paulo Maluf Administration (1993-1996)/Celso Pitta Administration (1997-2000)

After the Erundina administration, there was a pause to the programs that had been created until then, and in their place, the housing project PROVER, known as '*Cingapura*', was implemented by the Paulo Maluf administration (1993-1996). This project was characterized by sporadic constructions and low architectural quality and was continued in the Celso Pitta administration (1997-2000), serving mostly for political propaganda in (Antonucci & Filocomo, 2012).

The Marta Suplicy Administration (2001-2004)

In Suplicy's first year in office, the federal Statute of the City (Law 10 257/2001) was approved in congress. In principle, this law implements the pursuit of social justice in the entire country, and, in order to reach that target, a number of urban planning tools were created to help municipal administrations in the development of urban policies.

The Suplicy administration adopted the concept of the then-recently approved federal legislation to create the first PMH (*Plano Municipal de Habitação* - Municipal Housing Plan) in the city of São Paulo, which ended in 2012, the year Kassab's administration developed the second PMH (Barda and França, 2011). The main objective of Suplicy's PMH was to create great fields of action in the city of São Paulo, which were to stimulate social and spatial inclusion of the low income population in the most valuable areas in the city (fontes, 2005:86).

The *Plano Municipal de Habitação* also established the guiding principles of the Suplicy housing policy, which were: the creation of the Municipal Housing Council (CMH) – a team of representatives of the government, civil society and members elected by citizens. They would evaluate the projects in development, the administrative modernization of the municipal organs and the search for partnerships to finance public interventions (Fontes, 2005:87).

They also developed a consistent plan of action in slum areas, squatter settlements and improvements in the housing developments built for the low income population in previous administrations. All of the projects developed by this administration strived at maintaining the families in the areas they already inhabited.

The José Serra administration (2005-2006) / Gilberto Kassab Administration (2006-2008 / 2009-2012)

According to França (2012), as a work objective, the focus of the housing policy of Serra/Kassab was to comprehend the relation between the city and precarious settlements. As a

result of this work guideline, they developed housing projects which aimed at, for example, solving urban problems which surpassed the limits of slum areas. The most successful programs were the urbanization of Cantinho do Céu, on the banks of the Billings reservoir (Antonucci and Filocomo, 2013), and the Renova SP program, which created work perimeters of approximately 4 million meters squared (Barda and França, 2011).

In addition to these large scale projects, they produced housing developments following urban guidelines, but which were developed as architectural projects. This is the case with the projects developed for the Heliopolis slum area.

Human settlement: Heliopolis

Currently, with its 41,118 people (IBGE, 2014) and 986,222 meters squared (Fontes, 2005: 53), Heliopolis is the second most populated precarious settlement in the city of São Paulo. Its foundation was quite peculiar: it was the result of an unsuccessful housing policy. Its development, similar to other cases in São Paulo, was the result of the rising search for lands by the low income citizens. In this case, it was a large plot of land near the city center, therefore well-attended by the urban infrastructure network.

History of the occupied area

The first ownership record of the area known as Heliopolis today appoints the Countess Álvares de Penteado as proprietor. In 1923, the city hall opened a protocol to subdivide and urbanize the area. This project was not implemented (Sampaio, 1991).

On April 23rd, 1942, the land was disowned by the Institute of Retirement and Pension of Industrial Workers (IAPI) in order to build housing units for its members, a common practice of the retirement and pension institutes (IAP's) of the day. 36 houses, from 141 to 697 meters squared were built (Albuquerque, 2006: 186).

In 1966, the retirement and pension institutes merged and the National Social Pension Institute (INPS) was created. As a consequence, the land became INPS property. During this period, approximately 423,000 meters squared were subdivided and sold to PERTOBRAS, the energy company of Brasil (Albuquerque, 2006:186). Nowadays, part of the area is still occupied by PETROBRAS.

Another part of the land was dismembered in 1969 by the governments in power to implement two public health units: The Heliopolis Hospital and a Basic Medical Center (PAM). The second unit has regional importance.

During the decade of 1960 and 1970, it was common for city and state governments to create temporary shelters for low income families removed from areas receiving public intervention – mostly for street and road building. In 1971, 150 families were removed from a public area, in Vila Prudente, neighborhood of São Paulo, in order to build an overpass. These families were sheltered in the Heliopolis area.

In 1978, more than 60 families were removed from Vergueiro, a neighborhood of São Paulo, for the construction of a new road for the city. A total of 210 families were relocated to temporary shelters in the INPS land (Albuquerque, 2006: 186). This area, a specific point in the land, can be seen in this aerial photograph made available by Fontes (2005).

With this new architectural intervention by the government, there was massive mobilization to occupy the remaining space in 1977. The dwellers of these shelters, workers of the Heliopolis Hospital and PAM, bought the areas from the “invaders”, who subdivided the area and sold plots illegally, forging landownership documents. This illegal activity encouraged the occupation of the area in record speed, and due to this, the temporary shelters were treated as permanent interventions.

A new subdivision of the land took place in 1978, when part of the INPS property was sold to the São Paulo state sewage company (SABESP). The land was acquired by the Company so that equipment could be installed for the structure of the Construction Program for Sewage and

Water Pollution Control of the Metropolitan Area of São Paulo (SANEGRAN) (Albuquerque, 2006: 187). This area is still occupied by the company.

It is important to mention that both PETROBRAS and SABESP had bought land from a dismembered area and built low density occupations with low urban quality in comparison with their surroundings. These areas can be considered urban barriers, thanks to the large dimensions of the properties and their lack of use.

In 1980, INPS takes legal action for a repossession suit in the occupied area, mainly due to the action of “*grileiros*” – a typical and common type of invaders land in Brazil that sell counterfeit land lots propriety for other people. The plea was granted in 1983. In 1984, the land was sold to the National Housing Bank (BNH). However, with the bankruptcy of the Housing Financing System (SFH) and the extinction of BNH, landownership was transferred to the Housing Company of São Paulo (COHAB-SP) in 1987. At this moment, the sum of the land area of Heliópolis reached approximately 950,000 meters squared (Albuquerque, 2006: 187).

Due to a series of irregularities (occupations linked to irregular subdivisions since the 1970s; consolidation of temporary shelters; population of workers of industries located on the margins of Anchieta road and Juntas Provisórias Avenue; migrations to be close to family and friends), in 1986, Heliópolis clearly shows urban characteristics which would reflect on the development of the area. Among other characteristics were irregular urban network, small lands with no regularization, small empty spaces, low quality housing units (especially in precarious brick and/or wood constructions) and the inexistence or precariousness of infrastructure (Luz, 2010: 03). These characteristics can be clearly observed in an aerial photograph from 1986 (Fontes, 2005: 75).

At that time, there were about 20,000 inhabitants organized in approximately 4,700 housing units, of which 51% were wooden and 49% precarious brick constructions (Fontes, 2005: 56). This initial precarious structuring of the area did not impede further population of the settlement, which continues to grow until today. However, from the 1980s on, urban development of the area has been mainly influenced by direct public action.

Figure 1. Heliópolis (Map by authors).

History of public policies for the area

Although this research concentrates on the study of post-dictatorship housing policy management, public policies for the Heliópolis slum area began in the Barros administration (1979-1982). Therefore, will be briefly described the public interventions from the end of the

dictatorship: Reynaldo de Barros (1979-1982), Mario Covas (1983-1985) and Janio Quadros (1986-1988). In sequence, will be listed the main public interventions of the period in question, which spans from 1989 to 2012.

During the Barros administration (1979-1982), after years of struggle, the Heliópolis residents' association were granted service from PRO-AGUA and PRO-LUZ, water and energy programs of PROMORAR, the São Paulo city housing program. These policies aimed at improving and/or implanting the public infrastructure network in slum areas. In this case, water and energy supply was taken to parts of Heliópolis and both were financed by BNH (Fontes, 2005: 68).

In Mario Covas' administration (1983-1985), there were few, inefficient public programs for the area. Amongst those were two failed attempts at creating the Housing Plan of Heliópolis and an attempt at hiring a social assistance team for the area, who were eventually removed due to alleged lack of work conditions (Fontes, 2005: 68).

Between 1986 and 1988, during the Janio Quadros administration, 276 "embryonic housing units" were built by contractors. They were basic residential units which previewed the possibility of inhabitants themselves expanding their units. The units were 24 meters squared each, located in 74 meters squared lands.

In addition, 43 vertical units were built with 16 apartments each, with a total of 688 housing units, attending the population with income above 10 minimum wages. At the end of the term, more than 1176 units started being built by collective action. However, due to litigation from the residents' association, only 318 units were delivered (Fontes, 2005: 73).

During Luiza Erundina's administration (1989-1992) in the democratic period, the first urban plan was implemented in the area: the Global Plan of Interventions in Heliópolis (*Plano Global de Intervenções em Heliópolis*). The strongest guideline of the program was to keep the families which lived in the area there during project execution. However, if a housing unit had to be removed due to precariousness, risk or infrastructure building, the families affected were relocated to another area of Heliópolis.

In that moment, 178 vertical units started to be built by contractors and 130 units were built by organized collective action. Of 308 units, only 120 were finished. Other constructions paused during the following Maluf and Pitta administrations (Fontes, 2005: 76).

During Maluf's (1993-1996) and Pitta's (1997-2000) administrations, vertical and standardized housing units known as "Singapura" were built in Heliópolis, as well as in other areas of the city. This program was called PROVER and it delivered 344 housing units in Heliópolis in 1998 (Fontes, 2005: 79).

In Suplicy's administration (2001-2004), 430 vertical housing units were built by contractors. 344 more were in construction, but had been sold before the end of the term. Her administration invested the most in the urbanization of Heliópolis, by attending 14,588 families and 75% of the total area. The urbanization project implemented water and sewage networks, paved the consolidated urban areas and created leisure and green areas (Fontes, 2005: 83).

In the Serra (2005-2006) and Kassab (2006-2008/2009-2010) administrations, Heliópolis, as well as Paraisópolis, São Francisco and Jaguaré, were considered areas of particular importance due to being the four largest precarious settlements in the city of São Paulo.

The governments sought to develop projects that enabled implementing an infrastructure network in the neighborhoods (water supply, sewage collection and public drainage networks), the removal of families from areas in risk, the construction of new housing units to attend the housing deficit of the area, street pavement and construction of public equipment (França, 2012: 35).

By the end of the term, 100% of the families living in these four slum areas had been attended with water supply and 80% with sewage collection through the official network. In addition, 15,843 families had obtained official ownership of the units they inhabited in Heliópolis and, in addition, 3,442 new units were distributed among lands A, H, K, SABESP, N, Rocinha and G (França, 2012: 34, 103). It is important to note that not all units were inaugurated during Kassab's term.

Analysis of the influence of housing policy management on the urban space

The study of the relation between society and urban space has been discussed and proven by different researchers in the area of urban morphology. We can briefly cite names, such as Manuel Castells, David Harvey and Henri Lefebvre, who have contributed to this area.

In the same manner, we can affirm that the creation of urban form is the product of human action and the process of transforming space and its results comes from the political, social, economic and cultural actions of each community (Antonucci, 2005).

However, in 2001, Whitehand criticized urban micromorphology in the sense that it “has not been widely investigated” (Chen, 2012: 135). And, based on Chen’s conclusion, we can affirm that this detailed study of the production of this urban space clearly points out the political, economic, social and cultural influences on urban space in general. The Brazilian studies which have been published lean towards this theory (Antonucci & Filocomo, 2012).

Based on this information, will be presented the case study on Heliopolis below. This phase of the research aims to identify the relations between urban policies and urban space production, represented by the construction of housing units for the low income population by the municipal government.

Selection of the analyzed project

Considering the limitations of one paper, was defined, for this publication, select only one housing development to present. Therefore, we defined a methodology which would gather the main architectural projects developed for Heliopolis during the established period.

The Angélil and Hehl’s work (2012) was choose as an initial reference for the selection because of their list with 14 finished or unfinished constructions for the precarious settlement in question. In this work it’s possible to find some of the most important projects for the area.

The production was organized by the authors as followed:

After analyzing the available material, we selected the land H housing development designed by the architect Hector Vigliecca and team, due to it being the only one to receive direct influence from completely different housing policy managements, therefore better to exemplify the possible political influences on the urban form.

Land housing development (2013)

Based on the images provided by Vigliecca and Associates’ office, made available by Arcoweb (ARCOWEB, 2014), and information from the São Paulo city hall and architect Marcelo Rebelo⁷⁸, we can recapitulate a brief history of the land H housing development area, making a morphologic analysis of the space and considering the political, social and economic influences.

The first public intervention in the area was during the Maluf and Pitta administrations, when they decided to provide social interest housing units on land H, Heliopolis. For this, they elaborated and executed the projects in the lines of PROVER (Singapura), idealized by the abovementioned administrations.

When the construction of the Singapura housing development began, there was a fire that destroyed the unfinished towers, and the work was interrupted. At the time, 5 towers had been built and were receiving finishing touches, while the foundations for the rest of the buildings

⁷⁸ Interviewed in the beginning of 2014.

were in progress. The PROVER development was not resumed. From then, there were unplanned interventions, detached from surroundings and with low architectural quality.

Table 1. List of construction

City Administration	Period	Housing Developments Built	Notes
Erundina	1989-1992	Development 113 (Land K)	
Maluf + Pitta	1993-2000	Cingapura / PROVER (Land L1) COHAB (Land L2)	
Suplicy	2001-2004	PROVER (Land A)	start: Pitta administration
Serra + Kassab	2005-2012	Development 0 (Land A) Development 1 (Land A) Development Ceratti (Land N) Pocket II (Land A) Development D and E (Land N) Development 4 and 5 (Land A) Edifício Comandante Taylor (Land K2) SABESP 1 (Land K1)	
Haddad	2013-2016	Land H Land G	start: Kassab administration start: Kassab administration

The combination of housing deficit, high expansion potential in slum areas, completely dissociated and already deteriorated urban space and available space for construction encouraged irregular occupation of the empty space left by the unfinished PROVER development (a characteristic of the housing projects from the Maluf and Pitta administrations 1993-2000).

This irregular occupation consolidated and lingered in the area for about a decade. During this time, the homes produced by the residents of the slum went from ground constructions to precarious buildings of up to six floors, built in brick.

In 2009, during Kassab's administration, there was a new project for the land H housing development, named Residencial Silvio Bacarelli, which was developed by the Vigliecca and Associates office. The project was finalized in 2012. During this process, the irregular housing units built on the land were removed and construction began.

The project developed by the architect Hector Vigliecca and team sought to preserve the almost finalized structures from the PROVER program and, in the remaining area of the land, they created buildings attached to the pre-existing 5-floor structures.

The design of the buildings, besides having more harmonious dimensions with the surroundings, created six small leisure areas, a big square – where there is a multi-sports court, lanes connecting every block and three streets accessing the development, solving drainage, water supply and sewage collection problems.

The area of the unfinished towers was recovered and finalized, completing the 200 50 meter-squared apartments.

Construction finished in 2013 and, according to the source, the project was capable of relocating all families initially removed for the Singapura project.

Figure 2. Residencial Silvio Bacarelli before last intervencion - Photo by Vigliecca e arquitetos associados.

Figure 3. Residencial Silvio Bacarelli nowadays - Photo by Vigliecca e arquitetos associados

Final thoughts

After studying the documents about the political decisions made in different historical contexts, it was clear how the preoccupations of each government were distinct as to the quality of the architecture and urbanism of the produced housing developments, as well as to their preoccupation in improving the housing deficit in the city (Antonucci and Filocomo, 2012) and implementing infrastructure in precarious areas.

The interventions in Heliópolis dating back from 1979, still in the dictatorship, denounce the distinct interests of each administration regarding housing policy management. We believe that this interpretation is made possible because the precarious settlement in question is today the second largest slum of São Paulo in population, therefore being frequently chosen by the different administrations for housing policy experiments and consolidating concepts of intervention.

In the case of the Residencial Silvio Bacarelli development, on land H, we can observe how clear guidelines can lead either to creating quality urban spaces which correspond to the area's social demands, as seen in the Vigliecca and team project, or to producing spaces with no urban relation with surroundings, such as PROVER, which was implemented in other areas of São Paulo as well.

It is clear, however, that the city's housing policy management influenced the urban form of the precarious settlements of the municipality and that is why guidelines must be created compatible with the reality of each area of the city, so that the idea of urban space production through political action in precarious areas is compatible with the aspirations, the history and the culture of the population.

The auto representative image as an agent of legitimation and incorporation of urban settlements in the city of Rio de Janeiro

Carolina de Hollanda

Universidade Federal do Rio de Janeiro, Brasi. Bauhaus Universität-Weimar, Germany.
Deutscher Akademischer Austauschdienst /DAAD; Coordenação de Aperfeiçoamento de Pessoal de Nível Superior/CAPEs, Washingtonstr. 44, 99423, Weimar, DE.
E-mail: carolina.hollanda@uni-weimar.de.

Abstract. *Social Housing is a highly sensitive social issue in Brazil, where there is an urgent need to develop strong building policies for large conurbations. With the objective of guaranteeing more security and access to dignified housing, was established the society's engagement and the practice of new strategies that enable a bigger commitment with the elaborated proposals. In this sense, independent initiatives that intend to form photographers in slums are accomplishing a bigger visibility in Rio de Janeiro and this pedagogical work represents a new dialogue with the inhabitants of informal areas. The inhabitants can contribute in an effective way to a housing and urban proposal more suitable to their aspirations. The image decharacterization language assumes here the guiding role of the research in the inclusionary housing, contributing to help to solve housing issues, pointed with the documentary look. The research attempts to investigate how such images can contribute to the development and evaluation of inclusive practices of public policies in Social Housing and how they may benefit from the community's perception of their own environment. In the interaction between dwellers and local photographers, the community can convey their aspirations more effectively and closely related to their local realities.*

Key Words: *auto representative image, inclusionary housing, urban planning, housing planning, urban settlements.*

Introduction

This Project originated from the author's reflections after working with “*Instituto de Terras e Cartografia do Estado do Rio de Janeiro/ITERJ*” (Land and Cartography Institute of Rio de Janeiro State)⁷⁹, and during the preparation of the thesis “*Salubridade na Moradia Popular em Assentamentos Rurais no Estado do Rio de Janeiro: uma análise a partir do Mutirão Campo Alegre*” (Salubriousness of Social Housing in Rural Settlements in the State of Rio de Janeiro: Analysis of the Campo Alegre Cooperative) for a Master's degree⁸⁰.

In both latter instances, photography was a crucial instrument for recording research in the field and vital in the subsequent analysis of the buildings environment. In the case of *ITERJ*, photography was vital to evaluate the transformation of the settlement following legalization of the properties and lands where they were built. As for the thesis, photography was invaluable to evaluate the physical conditions of buildings within Campo Alegre, undertaken with methods developed by the “*Rede Brasileira de Habitação Saudável RBHSQ/Fiocruz*” (Brazilian Network of Healthy Housing).

⁷⁹ In the period 2003-2006 with the assistance of “*Fundação Carlos Chagas Filho de Amparo à Pesquisa do Estado do Rio de Janeiro/FAPERJ*”, the work aimed at mapping the housing and infrastructure conditions of three settlements regularized (legalized) by ITERJ in the metropolitan area of Rio de Janeiro.

⁸⁰ The focus was to investigate a cause-effect relationship between housing and health conditions as well as their influence in the development of the Campo Alegre settlement.

³The photographic materials enabled the development of a dialogue between different disciplines within the RBHS/FIOCRUZ research center.

As one evaluated the extensive photographic material from the two projects, the question arose as to whether the importance of photography should be investigated beyond its role as supporting instrument during scientific investigations. After all, the multitude of images illustrated clearly the subject matter and, more importantly, those images triggered new lines of questioning.

Local “people’s photographers” are becoming commonplace in Rio de Janeiro, where some projects in slum areas encourage locally resident photographers to create their own images to represent the interests and aspirations of their communities. This development enabled a healthy dialogue within the communities in addition to creating opportunities in the jobs market. Such documental images provide, above all, a educational and professional perspective from those who live in these places, thus representing their reality.

In any case, images also reveal conflict areas in the language used by interested parties regarding the city and social housing. Thus, the reach of Photography in the interpretation of buildings, housing and urban areas in the modern city constitute the focus of this project.

Multi-disciplinarity: photography, architecture, urbanism and visual language working together

Bearing in mind the author’s dual professional expertise – Urbanism and Photography – the intention of the current research is to focus on the dialogue between these two different disciplines. As will be seen, architecture, urbanism, photography as well as some other areas of visual anthropology will be explored together in the search for common grounds within the topic. From Morin (2010), we learned the importance of “inter- poly-trans-disciplinarity” in scientific research. The sum of human knowledge generates a global perspective - inter- and trans-disciplinary - research that releases one to trade and cooperate freely: *“intellectually, disciplines are fully justifiable, since they remain a field of view that recognizes and conceives the existence of links and solidarities. Plus, they will only be fully justifiable if not hiding global realities”* (Morin, 2010:113). In this sense, this study proposes to go beyond the boundaries limitations of any one discipline.

Expanding on the relationship between places and cartography, Seeman (2012) reminds us that the written description of places in maps is heavily influenced by whoever writes the piece. Thus, there is a dialogue between scientific and the human tradition in cartography. The winning proposal narrows the scope of the two opposing views: one that fits between the standardized tests and questionnaires, in order to give a scientifically accurate (quantitative research) and one that requires more open, flexible, or as the author calls “the most inventive” (qualitative research) .

Multi-disciplinarity, therefore, guide us down a path where photography, architecture, urbanism, and visual language work together. Thus, one would expect to reach an outcome that sums different disciplines to provide us instruments to achieve a housing and urban policy for the benefit of society.

Although the value of images still finds critics in Academia (Kossoy, 2001), its merits as a document have been recognized through the constitution of pivotal archives and in institutions dedicated to images as historical, anthropological and ethnographic sources of information.

The value of the documentary photography

Documentary photography found its place in the course of history from the time images were created. There are many examples where documented imaging demonstrates its relevance in understanding urban transformation. Even recently, there are authors from different fields of knowledge, who are keen to extol the value of Photography in documenting change.

In Architecture and Urbanism too, several authors have acknowledged the value of photography in the search for understanding the landscape and the transformation of urban spaces. John Collier, Kevin Lynch, Vilém Flusser and William Whyte and are outstanding examples that Photography is a validated historic and documentary source of scientific quality.

Emerging in the second decade of the 19th century, Photography adapted itself to the urban language from the very beginning, and was further developed in modern cities (Rouille, 2009). Product and instrument of urbanization since its creation, product of industrial society and, with the expansion of cities, Photography showed to be predominantly urban from its inception. Photography also provided visual records for scientific research, artistic creation - expressed in different languages and styles – and for social memory of societies; and almost a century after its birth, it provided a visual memory of conflicts and war events registered by photojournalism.

In 1935, the Farm Security Administration (FSA)⁸¹ of the USA represented a pioneering work and one of the most significant visual documentation of history by bringing together a team of renowned photographers (Dorothea Lange, Walker Evans, Russell Lee, Arthur Rothstein, Gordon Parks among others) to witness the life of farmers affected by the 1929 financial crash. The latter constitutes one of the largest and most important photographic North American collections from the early 20th century, consolidating the concept of photo-documentation.

Photography gradually became recognized as a documentary tool of great historical importance, acquiring social function and visual evidence in the major events taking place around the world.

In Germany, during the Weimar Republic in the early 1920s, the photographer August Sander with the Group of Progressive Artists in Cologne (Kölner Progressive), began his extensive work of cataloguing contemporary German society through a series of pictures. Sander developed the “People of the 20th Century”, essentially a cross-section of society during the Weimar Republic. The series was divided into seven sections: The Farmer, The Skilled Tradesman, Woman, Classes and Professions, The Artists, The City, and The Last People (homeless persons, veterans, etc.). The latter covered the crucial period of economic and social transformations that occurred in the country between unification (1871) and the first three decades of the last century (Rossi, 2009).

In Brazil, Pereira Passos (Mayor of Rio, 1902-1906) intended to record and show the changes of his administration through the image. Marc Ferrez (1843-1923) used photography extensively when he took part of the Geological Commission which documented the north and south of Brazil, while Augusto Malta (1864-1957), a documentary photographer working for Rio’s Municipality, recorded changes in the urban landscape of Rio in the late nineteenth century (Rouille, 2009, p.29) . During the government of Pereira Passos, Malta was responsible for documenting the transformation of the city in relation to delays of planned works as much as to the grandeur of the new features.

Sebastião Salgado, a Brazilian social documentary photographer and photojournalist, devoted many years recording the lives of socially excluded folk, such as the “*Movimento dos Trabalhadores Rurais Sem-Terra/MST*” (Landless Rural Workers Movement). Salgado contributed greatly to the development and dissemination of “photo-complaints”. Between 1986 and 1992, Salgado focused on rural workers, and between 1993 and 1999 he authored “The Children: Refugees and Migrants” (published in 2000). César Barreto, official photographer of the Municipality of Rio de Janeiro, currently documenting the changes ongoing in the city in preparation for the 2016 Olympics. Contemporarily, Boris Kossoy focuses on the value of photography to witness and document history, while Cristiano Mascaro has recorded the

⁸¹ An institution created by President Franklin Roosevelt, under the leadership of Roy Stryker with the mission of providing support to small farmers and rural communities during and after the Great Depression.

changes in São Paulo as a city and its architecture. These are a few examples of Brazilian photographers who have dedicated themselves to Photography in its documentary value.

Images initially registered chemically and now registered digitally in photographs, are thus highly effective tools for scientific research, and they had their role legitimized by enhancing our understanding of urban life and of the relationships between urban dwellers.

The participative management and the role of the Photography in a social housing planning

The value of images as vital elements in the pursuit for understanding the landscape and the transformation of the urban areas - within Architecture and Urbanism - has been investigated before. Researchers also used de-characterization of images as a means to understanding cities under construction and the relationship of the dwellers of a given space⁸². In Architecture and Urbanism, renowned authors have already spoken about the value of the image as a vital element on the pursuit for the understanding of the landscape and the transformation of the urban areas. Many researchers also used the image decharacterization discourse as the main way to a better understanding of the city under construction and the relationship of the inhabitant with the space.⁸³

The news here, therefore, is in the fact that the research proposes to Photography a new role in the popular areas investigation. Starting from the original experience of the programme “*Imagens do Povo*”, this project intends to demonstrate that it is possible to attain a satisfactory result in social housing policies through participatory management, whereby photographic material helps focusing social realities and aspirations of slum-dwellers⁸⁴. In short, Photography can play a pivotal role in generating and implementing social housing policies.

In the modern word, cities have suffered significant transformations. With the vertiginous urban growth and the disordered occupancy of the land, the current tendency is that appear more precarious areas, aggravating the vulnerability risk context. As a result, features like the housing deficit and inadequacy became the main issues to be solved in housing programs.⁸⁵

In Rio de Janeiro State, the lack of housing and basic sanitation policies have resulted in tragedy over the last two years. Rain devastated large areas of the cities of *Nova Friburgo* and *Teresópolis*, due in part to the intense building in areas bordering rivers, which are forbidden by law to be built on (“*non aedificandi*” areas)⁸⁶. In Niterói, the second largest city in the state, houses built illegally on landfill sites were destroyed by the rains. Yet, in several neighbourhoods of Rio de Janeiro houses are still being illegally built on hillsides that are unstable and without services (electricity, sanitation), with great risks to health and life, notwithstanding the environmental damage of such occupation. In the aftermath of these

⁸² Lynch, White, Collier, Kossoy and Mascaro are examples of authors referred to in this research (see “Bibliography”).

⁸³ Lynch, White, Collier, Kossoy and Mascaro are some examples of authors to which this research will refer (see “Bibliography”).

⁸⁴ Related to agricultural policy, the Ministry for Cities created in 2005 and the Participatory Directing Plan Campaign aimed “to create the means to generate resources for investment in housing and urban infrastructure.” (Bonduki, N.; Rossetto R.; Guilardi, F. H., 2009).

⁸⁵ Anna Tibaijuka, ONU’s subsecretary and executive director of the Programa das Nações Unidas para os Assentamentos Humanos (Un-habitat) (United Nations Program to Human Settlements), in interview to the IPEA’s website (2010): “(...) the continuous growth of the cities demands new solutions and public policies that can join suitable housing with access to goods and services, and to promote income generation to a population contingent that are still migrating from rural areas to the cities, looking for better opportunities and life-quality” (Website: IPEA, 2010). IPEA. Available at <http://desafios.ipea.gov.br/index.php?option=com_content&view=article&id=1369:entrevistas-materias&Itemid=41>. Access on: 03/03/2012.

⁸⁶ Areas considered as high-risk of flooding and, hence, forbidden to be built on.

disasters, the local population demanded new strategies to deal with building safety and access to decent housing⁸⁷.

One of the issues debated in the “participative management” of the last decade is whether democratic participation - proposed in the National Housing Policy – actually encourages society’s engagement in public policy. Participative management is predicated in all interested parties actively participating in the planning process. However, there is no effective space or forum for dialogue and reflection between the body politic and the communities. In this regard, the training of locally (slum) resident photographers represents one such line of dialogue with the inhabitants of these areas. Other than “Imagens do Povo”, the “*Núcleo de Antropologia e Imagem*” (Nucleus of Images and Anthropology)⁸⁸ and other research work such as “*Iconografia das Favelas Cariocas*” (Iconography of Rio Slums)⁸⁹ are examples of institutional projects aiming at greater interaction with communities and social movements, in order to promote debate about living, working and housing conditions of society’s poor.

Housing – a major issue: how can the auto-representative image be a contribution?

Cities undergo transformations along their history, the pace of which has increased in recent times. With rapid urban growth and disorderly occupation of the land, the current trend is the occupation of areas that in varying degrees may be unsuitable for inhabitation, which brings a concomitant increase in occupation-associated risks. Thus, housing deficit and inadequate housing became major issues to be addressed by housing programmes.

In order to ensure access to suitable housing, participatory management is paramount, whereby involvement of the local communities allows a greater commitment by these communities to the proposals set out in housing policy plans. The concept of democratic participation published in the “*Política Nacional de Habitação/PNH*” (National Housing Policy, approved by the Council of Cities, 2004) establishes that all interested parties should participate in the planning process. However, the political elites responsible for housing and urban development have not yet established effective forums for dialogue with the communities in Brazil.

A new way of evaluating the different spaces within cities is through Photography, which became common practice among low-income neighbourhoods in Rio de Janeiro city. In this regard, training popular photographers within the slums represents a new opportunity for dialogue with the residents of informal areas of the city. Through the visual records of their own reality, the locals are starting to contribute effectively to housing and urban proposals in a manner that is more in line with their aspirations, while providing a vision that is more closely linked to the reality of their living space than the vision of whose is observing from ‘outside’. As a bonus, photographing gives to the economically disadvantaged a possibility to changing from being “objects of representation” to being “authors of their own representation” (Gama, 2012).

The agency of images “*Imagens do Povo*” (People’s Images) started in the 1990s, made a new proposal, namely to foster a new image of the “*favela*” (slum) and to increase the self-esteem of the youth of Rio’s *favelas*, by including them in the jobs market. More importantly, they proposed to give the local youth the chance of portraying the spaces they inhabited through

87 According to this document (Ministério das Cidades: 2004: 29), the NHP is in line with the Constitution that considers housing a citizen’s right, which together with the Cities Statute, establish the social role of property, among other civil rights”. (Bonduki, N.; Rossetto R.; Guilardi, Flávio Henrique, 2009).

their own perceptive. We refer to the above-mentioned images agency People's Images⁹⁰ (created under the auspices of "*Observatório de Favelas*" – Slums Observatory⁹¹) as the germ of the ideas for the current work. The main aim of this project is to analyse how locally generated photographic images (of slum areas) can contribute to housing and urban development. The project also investigates images as a *critique* of public programmes and how images may help planning of social housing with citizen inclusion. Such documental representation is the guiding light to this research in investigative analysis of social housing, cities, and their urban context.

By means of the generated records of their own reality, slum dwellers start to contribute effectively to housing and urban proposals that are more suitable to their aspirations and living space. The language of image de-characterisation takes in this case, effectively, a guiding role in the investigative analysis of social housing in the city, contributing to solving housing issues highlighted by the documentary materials.

The results of the current research may contribute towards the development of public policies directed towards urban housing programmes to identify and offer more urban territories with infrastructure.

The origins and pathways of urban (in)formality: towards an understanding of local dynamics and agents of change within a favela in Rio de Janeiro

Mónica Guerra Rocha⁹²

Kungliga konsthögskolan (Royal Institute of Art, Stockholm)

E-mail: mfmguerra@gmail.com.

Abstract. *“The fact is that the segregated social space that characterizes Rio de Janeiro today had the public power as one of its director agents”. (Redes de Desenvolvimento da Maré, 2013) p.24*

Subnormal settlements, informal settlements, favelas, slums - the words remind us of places of non-planning, the opposite of the formal city, lack of infrastructure and services, poverty and segregation. In Rio de Janeiro around 22% of the population lives in informal settlements. These territories have structural characteristics that diverse them from the rest of the city, but that also diverse them from each other. Although they have been historically understood as the informal place, segregated and separated from the rest of the city, they are in fact territories that result from the formal city, dialogue with it and build its own dynamics as an autonomous and specific urban place. This research looks for the historical background that built up the favela of Maré, in the North region of Rio de Janeiro, with approximately 130.000 dwellers. This territory may be considered as a paradigmatic example on how different agents of change build the morphology of our territories. It is a complex of 16 favelas, each with its own background and particular form, built upon a landfill ("maré" is the portuguese word for "tide"), delimited by 3 of the most important traffic ways of the city. The aim of this research is to understand the agents and context of construction of this territory and its inner variations by questioning the dialogues and dichotomies that determine its urban morphology. It tries to look at the urban form as a complex result of human, social, political, geographical and infrastructural dialogues, and brings ideas for a new perspective over these places, focused more on their inner processes rather than on their products, as places of adaptation: adapted and adaptable.

Key Words: informality, favela, urban dynamics, adaptation, Maré

Overview

Maré is formed by 16 different communities. Each of them have their own story, their own traumas, challenges and inventions. The physical result of the planning processes (even though when those processes were not called as being a planning strategy but a temporary solution for other urban objectives) were in the end, just the first tip for the development that followed. Being mainly a mangrove area, with only one hill, and having historically passed through different political moments and political understandings and initiatives towards the favela, one may say that urban growth and planning bind together as a response to its own urban context – physical, social, political.

The aim is not only to define the agents of change, the objective causes of morphological conceptions, but to make a proposal for an understanding of urban dynamics where the form follows and is followed up by local inventions, wishes and dreams. But coming from the

⁹² This paper and its conceptual interest come from a direct contact I had with Maré, while collaborating with the NGO Observatório de Favelas, and was done supported by the Royal Institute of Art - Stockholm.

Some impressions presented here come from the empirical experience and local informal observations, that opened up reflections and interests about the urban structure of these multiple territories inside Maré. Therefore, some impressions here are mostly founded on a daily basis perception and further reflexion, that are still on the working process of finding the most possible complete theoretical support.

research question, we shall understand what is that about informality in Maré? Can we really talk about an informal settlement and by doing that, consider that it is a result of not planned processes? As we will see now, Maré is a very clear example of how public decisions and understandings of the “favela as a problem” turned out to be the planning process in itself.

By getting closer to its own stories and history, the main questioning that is pushed up here is if territories like favelas, and specifically Maré, can still be understood and classified as being informal, slums, or any other classification that detaches them for the rest of the “formal”, “legal” or “beautiful” city, or if this paradigm shall be urgently shifted in order to build a more coherent understanding of these territories as deeply related to the city as a whole, dependant from political, economic and social moments, as contemporary territories of urban development. By shifting this paradigm, one may also question the role of planners as agents of change, and the necessary political positioning upon these places in order to achieve an integrated and democratic city.

Classification and conceptualization: regional approach always as a comparative model?

For a theoretical approach of place: applying the anthropological concepts of Michel Agier

In anthropology of the city (2011), Michel Agier, when talking about the urban knowledge of anthropology, speaks about three categories of approaching the urban themes in anthropological research. He considers that all the knowledge taken from the city is always a partial knowledge, based on metaphor, comparison, dialogue, and other inductive perspectives of research. He is interested in the process between the observation and the construction of urban knowledge, the way to get to urban theorization from empirical experience.

He says that there are regional, situational and reticular approaches to the urban anthropological questions, and remembers us that urban investigation has its starting point within the context of Chicago as a fast growing city with emergent new issues.

From the research question of this paper, I find it interesting to take a departure from Agier's position, once that what is proposed here is an understanding of the partial perspective that is being taken upon the understanding of the favela as the “other” territory that is informal, segregated, poor, and resulting from the absence of the state. What is proposed here is a more objective perspective of the evolution of the territory of Maré as an interdependent and integrated part of the city of Rio, and a fundamental testimonial of the history of the city.

“Space has been, through time, designated to answer to specific functions that vary according to the needs of the social organizations of each time. From this perspective, the city results, unfinished and in transformation, from interventions that are regulated by different systems of social and economical values.” (Resende, 1982) p.19

The regional perspective is, according to Agier, where the social control is built. The socio-spatial classifications organize the affirmation of relative differences, and never of absolute identities. He supports that there are natural areas of segregation, related to the origins of the population, reaction, age, or one may add, related to economical situations of a given population. However, the territories where natural segregation may occur, then level up into moral regions, reconstructed in the imaginaries of the whole population – the building of the imaginary city, the imaginary cartographies. In the individual perspective, it would be considered when the individual becomes a person, as the social status is defined, together with social distances. As I try to bring the theory to an urban morphological perspective, it would be when the territory becomes the place. The definition of place is done by all urban actors, from decision makers, to planners, to the population, and the definition of the place needs to have the whole city as a referee.

This process supports the building up of social distances above spatial distances, the creation of relative identities and the possible understanding of the city as a patchwork of different and well defined places that somehow close in themselves.

These classifications open the door to potential duplications, or definitions by opposition of two different classifications. According to Agier, defining a place with bad reputation and building a stigma around that specific area can be a way to classify other areas as being areas of social success, by opposition.

This regional approach of urban reality can be easily understood in the evolution of the definition of the favela – and specifically of Maré – as a place: the favela vs the city, informal settlement vs formal city, ghetto vs legal city, slum / shantytown vs structured city, periphery vs center, zona norte vs zona sul (North zone vs South zone), and lately the understanding of it as a neighborhood, but one that needs to be integrated to the rest of the city (considering it is a different neighborhood, and shall be integrated through “pacification”).

“Taking advantage from that uncertainty of boundaries, the “regional” point of view would win, I think, in being applied to any space, independent from its limits or its scale. By doing so, it could be registered the way how a place is defined by the urban actors, whomever they are (from the urban planner to the inhabitant of an alley). This sense of place undertakes the whole city as a referee context.” (Agier, 2011) p.67

Besides the regional approach, Agier describes what is the situational and networking approaches. Both approaches build the understanding that the urban relations and interactions are not determined only by the place where they occurred, from what they can be at least, influenced. The specific situations of interaction vary among the same space in different periods of time, and can give to these spaces different identities and classifications. Also the networks built upon specific urban areas are fundamental to understand the dynamics and to build on knowledge about a specific place.

So, one may say that the regional classification is always relative to a specific context, and that urban interactions exist upon and further from the its regional condition or categorization.

Foreplay and the foundation of maré – could have it been some other way?

Where does the Favela come from?

Let's start the story in 1893, even though we could go even more backwards and find possible bridges between the favela and its stigma, its creation in the end of the nineteen century and the slavery history of Brazil. But let's start it from 1893, that was the time when the very first house occupied the “Morro da Favella”.

“The episode of the destruction of Cabeça de Porco became one of the initial marking points of a whole way of understanding the management of social differences within the city. Let's locate the two fundamental points of that way of dealing with urban diversity. The first one is the construction of the idea that “poor classes” and “dangerous classes” - to use the terms of the XIX century – are two expressions that talk about, that basically describe the same reality. The second one refers to the appearing of the idea that a city can only be “administrated”, which means, managed according to technical criteria alone.” (Chalhoub, 1996)p.19/20

The cortiço of Cabeça de Porco was the first known episode of destruction of these tenements of the urban poor, but the story repeated in many other areas of the city. The cortiços were seen as dirty and immoral areas, and through hygienist arguments, they were removed. The inhabitants, needing to find places to settle, started to go to the hills of the city and build their own houses. The city was living a moment of great immigration, and also of fast development and the poor ones could not afford living in more privileged areas of the city.

It is in the end of the century, specifically in 1897 that the Morro da Favella is occupied. It is important to understand that the issue of housing in the city and the incapacity to deal with the urban poor dated backwards, before the word “Favella” was even used for the first time Key Words: Saverio Muratori, Ludovico Quaroni, morphology, typology, Rome School of Architecture.

The Morro da Favela has a very well known story: it was the place where the soldiers

coming from the battle in Canudos in Bahia settled when they arrived in Rio and did not have housing provisions as promised by the government. Favella is the name of a plant that is very popular in the region of Canudos, and because of the soldiers occupation, the area was known with that name.

So, the first generalist identification and classification of these territories is, in fact, the name of a plant, and is a word that does not carry in itself any morphological considerations or any pre-conceptualizations of informality or marginality.

In the beginning of the XX century, Pereira Passos, the “tropical Haussmann” (Valladares, 2005) started great urban works in Rio, and defined a very clear urban positioning. It was known as the period of the “bota abaixo” (“throw it down”): with the construction new big infrastructures in the city centre and the beginning of the demolition of Morro do Castello, demolishing one of the biggest cortiços in the city. Already in this early moments, Morro da Favella was already seen as a place of great violence, lack of basic infrastructures, sickness and immorality. This is just the beginning of a big story that repeats all over the time, and in Maré (occupied only in the 40's) it has its specific urban impacts.

Where does *Maré* come from?

Figure. 1. Maré – the area in 1929 (Guia Brigueiet map) and in 2009 (google maps). Down, the Ilha do Fundão, where is the university of Rio (UFRJ) and in the center (between the big yellow line that is Avenida Brasil and the shore) Maré. Sobrepositon work by Êisdur and published at Êisdur (2013).

With the revolution that happened in Brasil in the 30's, the industrial bourgeois ascends in social class and capitalism is expanded in Brasil. It is the end of oligarquies, and the beginning of an economy based on industries. With the world crises of 29, Brasil focuses on its internal market until the second world war, when there is a new phase of economical growth: great exportations, fewer importations and greater demands on its internal market. In 1937 starts the “New State”, with the main figure of Getúlio Vargas in the power. He starts an extremely populist government, that in fact supports the industrial bourgeois against the working class. When WW2 ends, Vargas tries to recover his relation with the popular classes, but the institutionalized powers of the bourgeois and the old imperialists do not allow it to happen. In 1945 Vargas is taken out of the government and Dutra takes power until 1950, supporting a new imperialist moment in the country. In 50 Vargas is elected, and in 54 he suicides and it is when Jucelino Kubitscheck becomes president, supporting the principles of development, on a progressist policies towards the greates capitalization of the countrys opening it to foreign investments and implementing industries in the country for durable products (it is a moment of great exoansion of the automobile industries in Brazil). Kubitscheck is also the president responsible for the construction of Brasília and moving the main city from Rio de Janeiro to

there, in 1960. In 1964 starts the military regime in Brazil, a dictatorship that will last until the 80's.

In this context, Rio faced a great amount of migrants from the 30's on, when the country faced great growth inequalities between different regions, and reinforced Rio and São Paulo as the main investment areas. People from all over the country were migrating to both cities, looking for working opportunities. Only on the 50/60's Rio starts to have fewer migrations than São Paulo, being until then the main destination of thousands of people, and in the 60's the city becomes the State of Guanabara, after the inauguration of Brasília as the main city. All these years of migrations to Rio had strong impacts in the city, that was not prepared to receive this amount of people.

“The consequent flow of migrations in direction to these points (Rio / São Paulo) brings as a consequence the growth of the population of favelas, that grows on a rate of 7% against 3,3% that refer to the population growth of the whole city. In 1960, the population of favelas reaches 11% of the total of the city, that is of 3,8 million inhabitants” (Resende, 1982)p. 50

It is in this context that the city of Rio is strategically planned to grow towards north, with great investments in industries. In 1946 Avenida Brasil is built and opens to traffic, and along its way several industries are built and start working. Years later, the university of Rio de Janeiro builds its new campus in Ilha do Fundão, nearby Avenida Brasil. In this period, the city had no housing provision for the new residents coming, and the areas available were of high prices in a city that was developing increasingly towards a capitalist and private strategy of the richest ones. The working class, mainly migrants getting to the city, needed to find housing solutions for themselves. One of the priorities was to be closer to their working places, in a period where transportation was already a growing problem. There was a continuous growth on the number of favelas of the city, on faster rates than the growth of the city of Rio itself. (Perlman, 2010)

A part of Avenida Brasil was built close to a mangrove area, that was vacant because it was not a desirable place for real estate investments. In this area worked, on the XVI century, the port of Inhaúma that was on that moment a very important port for the transportations between the centre of the city and its north area. Also, this area was exactly between the new avenida Brasil being build and the future University at Ilha do Fundão.

This area of no interest for the wealthiest, was a very strategic place for the working class. (Vaz & Jacques, 2004) On the early 40's, Mrs Orozina decides to settle on the only elevated area within the mangrove, and for decades, the place was enbanked, occupied, developed, structured, transformed and adapted. Being built upon the water, it was named Maré (tide). And so the story goes from here.

A morphological trip: addressing processes of urban development in the 16 favelas of Maré

This section will focus on the history of the favelas of Maré. The work of Lilian Vaz (Vaz, 1994) was the main source of this data, together with the maps guide of Maré (Redes da Maré; Observatório de Favelas, 2012) and the publications of Redes da Maré (Redes de Desenvolvimento da Maré, 2010 and 2013) All the chapter has reference on those works.

Avoiding the classical classification of “formality” vs “informality”, that we aim to dissolve in this paper, the communities of Maré will be introduced and its history presented based on its *form*. We consider that informality can never be the absence of form, but the lack of understanding of different logics of space structuring. This comes from the understanding that both time and space are social inventions, built by specific logics of society (Damatta, 1997).

So, based on form, communities are presented according with two different criteria: regularity vs irregularity, and within each group, they are presented chronologically.

Figure 2. The evolution of Maré in a period of 50 years (source: Jacques 2002, design by Pedro Seiblitiz, taken from (Vaz & Jacques, 2004).

The irregular places

Morro do Timbau, Baixa do Sapateiro, Parque Maré, Roquete Pinto, Marcílio Dias

The irregular territories within Maré have a common basic story. They all result from spontaneous occupations, are usually the oldest areas occupied in Maré and have stories of struggle against evictions. In these areas it is very clear the inventive capacity of the populations to find strategies in order to fix themselves and build their own urban environment out of the different challenges that they need to face. These places are a great collection of memories from the occupation and the removal attempts, as well as from the opportunist episodes when public forces tried to take advantage of the weak political conditions of the urban poor. In these territories we may also find great lessons of other ways of thinking urban priorities, difficulties and solutions for very concrete and specific problems. In Maré history tells us that people didn't occupy the land, but they built their own land to fix their presence and rights within the city. It is a construction of identity, built from almost nothing but the need to stay, or what one could understand as the capacity to organize urban structures around the need for urban life.

40's and 50's

Timbau and Baixa do Sapateiro (located side by side) are contemporary considering their occupation, but it is usually said that Timbau was probably the first territory being occupied⁹³. The area known as Praia de Inhaúma was already place for some fisherman communities, on the fringe between the hill and the water, but it was on the 40's when people started occupying the hill and giving it the shape we see today. Timbau, Baixa do Sapateiro and Praia de Inhauma were, one may say, the origins of Maré, and neighbors of each other in a continuity of development – this continuity is very clear when observing the map of the areas

⁹³ The population argues that Timbau was the first area occupied, but some official sources (SAGMACS) say that the area where is Baixa do Sapateiro is occupied since the 20's. (Vaz, 1994)

Being the only elevated area of Maré and this was a fundamental condition for the first occupations, since it was the only solid area to start occupation – Maré was a huge mangrove area in that period. Baixa do Sapateiro itself first started to be occupied in its hill area, the borders between Timbau and Baixa were blurred, and only later people started to go to the mangrove land and build there. This topographical condition supported the definition of the first occupied area, and its morphological organization is very related with the fact of it being a hill, with similar territorial distributions than in other hill favelas of Rio. The first inhabitant of Timbau, Mrs. Orozina, assumed that she knew from the first moment she was occupying land without allowance, and her family self built their first wood house there. In the next years more people came and settled in the area, and in the 50's, Timbau was already becoming a more dense area. (Vaz, 1994)

This has directly relationship with the construction of Av. Brasil in 1946 and the University of Rio in Ilha do Fundão, in 1950. It was the period of great industrial investments in the city, a planned development towards north based on industrial development, the area of Maré was located exactly between the two projects and these infrastructures demanded a great number of workers. In Rio, in this time, there was a great movement of migration towards the city, from other areas of Brazil, mainly from the country side of the northeast, where people were suffering from droughts. It had impacts on the increasing of favelas and its population: the favela population grew in that period 7%, while the city's total population grew 3,3%. In 1960 11% of the city inhabitants were living in favelas. (Burgos, 2006)

The population was occupying the area at first according to their individual needs, and the houses were first built with wood. Because the area was structured, as time passed, the inhabitants of Timbau started to build better infrastructure systems – while in the other areas people were struggling to live on stilt houses, and investing on embankment works. Also from the 40's is the occupation of Marcílio Dias (first called as Praia da Moreninha), an area quite far away from the rest of Maré⁹⁴, where fishermen already lived in stilt houses. (Redes da Maré; Observatório de Favelas, 2012)

It might seem weird, but in the 40's Rio was living a moment of strong favela removals. The código de obras (code of construction works), created in 1937, proposed the elimination of the favelas and ignored them from the maps. It was then forbidden to improve the houses in favelas and to build any new house. As a solution, the mayor Henrique Dudsworth starts the projects of proletarian parks to re-locate people living in favelas. (Leeds & Leeds, 1978) In these proletarian parks the daily life was strongly regulated, with great vigilance, considering that the people from the favelas needed to be civilized. These proletarian parks were supposed to be temporary but ended up in being permanent and people stayed until they were evicted from there. From 41 to 43 there were 3 proletarian parks built in the city, on a clear statement of the authoritarian populism of Getúlio Vargas government – deeply care about the proletarians, with great control over the urban poor, in exchange of populist measures.⁹⁵

It was in this context that one can understand the fundamental role of the military for the history of Timbau and its present condition: in the 40's, the army settles in an area nearby Timbau and they start to control the development of the area. They argue that the area of Timbau is their property and started to ask for payments from the population. The inhabitants

⁹⁴ There is a military area separating physically Marcílio Dias from the other parts of Maré.

⁹⁵ It is important to remember that in 1937 the country faced a *coupe d'etat* that initiated the Estado Novo (the new State) regime, a dictatorial period, centered in the image of Getúlio Vargas. The Estado Novo lasted until 1945, and it appeared within the context of the growing of an industrial bourgeois. It was a populist government, and ended up in being the opposition of the industrial bourgeois and the organized and “official” working class, against the informal poor workers. When Vargas tries to focus on its popular basis, the imperialism and its actors don't allow it and he is taken out of power in 1945. Vargas returns, elected, in 1950, after 5 years of an imperialist government of Dutra. In 1954 Vargas suicides, and Juscelino Kubitschek becomes president, starting a progressive government opened to international investments.

needed to have a strong relation with the army, considering the threat of removal that was present in this period in favelas all over the city. In 1947 the municipality orders the removal of the houses of Baixa do Sapateiro, when there were already some embankments done and stilt houses in the mangrove area.⁹⁶ In 1947 the mayor Mendes de Moraes created a commission for the extinction of Favelas, but the commission has as its only effective final product the construction of a Census of Favelas. However, it was a moment when Favelas were seen as an issue to face – in 1947 is created the Foundation Luis XIII, attached to the church but with support from the government, whose main role was to recover the favelados and “save” them from the communist threat within a politics of high control. Also in 1948 Carlos Lacerda⁹⁷, that in that time was a journalist, starts up what he calls “The Battle of Rio”, understanding favelas as a national problem, rather than only a municipal one. (Leeds & Leeds, 1978)

Although favelas development were strictly controlled, in the 50's the area of Parque Maré (located between Nova Holanda and Baixa do Sapateiro) starts to be occupied (it is Maré's 3rd favela) as a consequence of the population growth, mainly resultant from the existence of new industries along Avenida Brasil. Parque Maré has also an spontaneous occupation and its irregular streets together with great number of full of alleyways that come from main streets, are mainly resultant from the processes of embankment done by the population in the 50's (similarly to Baixa do Sapateiro). The area was occupied first close to Av. Brasil, in what is today Rua Teixeira Ribeiro, and differently from Baixa or Timbau, the area of Parque Maré was completely mangrove land, and the first occupied areas were the ones where there were already some small entrances of land. Its morphological structure has its origins in the fact that the bridges built above the mangrove were the origins of the embankments done, defining the streets of the area: Rua Flávia Farnesi was the first resultant from the embankments, but many other streets were built upon the mangrove. (Vaz, 1994)

In 1955 Roquete Pinto is occupied. It is a landfill area, with constructions first built out of wood, later replaced by brick buildings, in the process of consolidation of the community. It is located north, separated from the rest of Maré, and close to Praia de Ramos, also an occupation from the 50's, when fisherman and some fish marketers lived in the area – known, at that time, as Maranguirú (mangrove, in TUPI language). There was there a beach and a small port. There, residents started to build embankments and wood houses, replacing the stilt houses. These two areas are located in flat areas and were both occupied in an spontaneous way. (Redes da Maré; Observatório de Favelas, 2012)

So one may understand that even if from 37 until the 50's favelas were being highly debated and its population controlled - the population needed to ask for allowance to do any improvement or construction in the area, until the 50's when building new houses was totally forbidden, it was one moment of great development in Maré. It was a development done with great struggling, persistency and patient, with the population rebuilding and re-inventing ways of staying in the area against all odds of the current time politics. This controlling and restrictive moment of the history of favelas in Rio is also a key to understand why Timbau is the community of Maré with the lowest density rates, related with several control from the army against new construction or development of the area. At the same time, from that relationship with the army, the residents started to organize themselves in order to fight for their need of improving the area and for achieving their property rights: Timbau has the oldest Residents Association of all Maré – started in 1954. (Vaz, 1994)

Baixa do Sapateiro ended up in not being demolished, and people kept on building their own houses in the night, and paid to the policeman that supervised the area for him to let them build. Houses were made out of leftover materials (construction materials, wood and metal) and the stilts were done 2 meters above land, with bridges connecting the houses. Later, as people were embanking the area, these connections turned out to be the streets.

⁹⁶ Maré had, in the end of the 40's, around 3500 inhabitants.

⁹⁷ In the 60's Carlos Lacerda becomes the first governor of the Guanabara State, after Brasília became the main city and Rio turned into a state, and developed a series of politics for controlling favelas.

When the police used to come and demolish some of the houses, the strategy of the inhabitants was, besides building them in the night, to have them occupied with children in the day, hoping the policeman would be sensitive to that and not take the houses away with children inside.

In 1957 the residents association of Baixa do Sapateiro is created with the purpose to build water provision and sewage networks, which happened in the 60's. Until the 60's the inhabitants improvised ways of getting water and sewage systems done by themselves. (Vaz, 1994)

It is important to locate historically the resistance of the population that, in a moment of great control and even forbiddance of building, kept on coming to Maré and struggling to fix themselves and develop the area. within this dual relationship of government with the favela, and maybe try to take from it some understanding of the processes that happened: the industrial investments and infrastructural construction of the city asked for great number of workers to be in the city, but the municipality didn't have the capacity to answer with proper housing provision. So, if in one hand the wish to clean the city from the favelas is politically present and represented through governmental actions, in the other hand the constant demand of workers supports the process of development of favelas in the city. Maré has both facts within itself: growing while struggling not to be taken away. This process of development led directly to its current form: intuitive, completely context-related (both topographical, geographical, political and sociological) with great priority in building individual housing, before planning or building common infrastructure.

The 60's

In the 60's, the policies relative to the favela, besides being pointed with external variations on its shape, is essentially the continuation of a policy of control, that goes back at least to the 30's. Sometimes that control is lined up of more populist adornments – for example, on the way of “urbanizing” in loco of favelas, but in some other moments it appears under a more repressive shape, as, for example, the total removal of favelas and the rigorous administrative supervision of the governmental housing units of emergency, called as proletarian parks" (Leeds & Leeds, 1978).

From 1968 to 1973 more than 175000 inhabitants of 62 favelas were removed and transferred to one of the 35517 new housing units built mainly on the north and west side of the city (Brum, 2012). This was done through CHISAM⁹⁸, an institution from the federal government, supported by the state government of Rio. On the 11th of May of 1969, the favela of Praia do Pinto, located in Leblon (one of the wealthiest neighborhoods in the south zone of Rio) burned and its population was removed to different housing units along the city. Since the 23rd of March that the residents were being removed, but the ones resisting the eviction were staying in Praia do Pinto, within the debris left of the houses already demolished. There was a great real estate interest in the area, and the politics of the government was once again, seeing the favela as a problem to correct by removing it and building low income houses in places far away from the city centre and the south zone. It is still not confirmed the origins of the fire in Praia do Pinto, but it is consensual among the residents that it was an initiative from the government to definitely clean up the area. One of the main arguments from CHISAM to

⁹⁸ CHISAM – Coordenação de Habitação de Interesse Social da Área Metropolitana (*Coordination of Housing with Social Interest of the Metropolitan Area*) was created in 1968, as an initiative from the federal government. IT had a single perspective over the favelas, understood as a problem to be eradicated, through the extermination of favelas in Rio. It subordinated COHAB to build housing complexes for residents of favelas. In that period FAFEG (Federation of Favelas of the Guanabara State), a strong association, was also transformed and started to support the state government, with some residents associations working in representation of the State (Brum, 2012). According to the sources consulted, this didn't happen with the residents associations in Maré, that kept on fighting for urban improvements and against removals.

remove favelas was that they were “urban abnormalities that act against the more primary principles of civilization”, so the urban argument was used to justify the removals. In the case of Praia do Pinto, the houses were all made out of wood and it lacked urban infrastructure, and this territorial fragility was used sometimes as a government argument, even though it was then clear that the main objective was to sell that land to private companies and build high valued housing blocks. (Brum, 2012) The episode of Praia do Pinto became a paradigm of the governmental action towards the urban territories of the favelas in this historical period, and a possible trauma for the residents of favelas, being understood and so dramatically treated as undesired in their city.⁹⁹

In this context, one of the objectives of the residents associations in Maré was to resist the attempts of removal that happened in the 60's by urbanizing and building stronger houses, and getting structured so they would have arguments for not being removed. Many brick houses were built in this period. Once it started being forbidden to build in bricks (by SERFHA and SMDS), people find strategies to overpass the rule and Baixa was consolidated in this period. (Vaz, 1994)

In 1957 there was a big fire in the whole community of Praia de Ramos that destroyed it completely. The area was rebuilt by the residents and in 1962 it was already a consolidated place. (Redes da Maré; Observatório de Favelas, 2012)

In the 60's some residents from Baixa moved to Parque União, a new area occupied and structured by Margarino Torres, an influent man that planned the occupation of that space. He took inhabitants from Baixa to start fixing the area in Parque União, and people could find better physical conditions there, where the embankment was already done. If on one hand Baixa and Timbau were already becoming structured and greatly occupied territories, Parque Maré greatest expansion was during the 60's, when the embankments started being built in the area, and people were already building brick houses and expanding towards the bay, on stilt houses. (Vaz, 1994)

Its morphology is directed related with the housing building processes, and the strategies of the house owners to ensure bigger land properties for their own: the houses were built quite far away from the toilets, built outside. As it was a mangrove area at first, the houses and the toilets were connected through a bridge, and by doing so the owner would mark on its occupation that the area between his house and toilet belonged to himself. Later on, the owner could think on selling portions of the area or renting them and having economic benefits from it. This is a very interesting strategy, that shows clearly how the residents did not only struggle to stay at that place and fix in the area even though they needed to make great efforts not to be taken away and to do great embankments, but that they also planned their occupation considering a long term evolution of the area, a consolidation and having future economic benefits out of that planning. In this case, it is extremely wrong to consider that these areas are informal and not planned, when the logics within their occupation are totally based on a very coherent and strategic planning thinking. The residents fixed in their formal territory their determination to stay and struggle (physical and politically) and also to develop further and consistently. It was then, one may say, a common interest of all the inhabitants to improve their territories, both for common benefits of having better urban infrastructure, for individual needs of having provision of services and the specific plans to improve their lives. One may then understand also that, by building their own houses and organizing their thinking, they planned to stay on the area with long-term perspectives, and improve their lives taking advantage of their own planning decisions.

Because of this organizational methodology, Parque Maré has its specific morphological asset. Some people coming to Parque Maré didn't have enough budgeting to build their houses and toilets outside, so sometimes they would build their houses side by side with a neighbor and

⁹⁹ Some residents testimonials of the fire tell that they were transported to their new housing units in garbage trucks, and many didn't even know where they were when they arrived in the new houses. (Brum, 2012)

use his toilet, through his bridge. In other cases, if both would have the opportunity, two toilets could be build side by side, with both bridges side by side. Once the embankments were done and the urban structure better defined, the bridges that before connected the houses with the toilets became the streets of Parque Maré: the single bridges may have turn out into small alleys, as doubled bridges became bigger roads.

So one may say that in Parque Maré we have a great example of how irregularity can result from planning if planning itself is focused on something else rather than in pre-determined forms and shapes. In parque maré there were no issues of alignment, spatial proportion or morphological pre-conceptions; people built as they perceived their best opportunities and priorities. The same way that happened with Baixa do Sapateiro, the houses were build and rebuilt, with the police coming and demolishing the built houses, and people putting them up once again.

As in whole Maré the houses were built without water infrastructure being the basic infrastructure done later on, after the area was occupied and establishing, usually with support from residents associations and among the community. The first sewage infrastructure was done connecting with the sewage network built in Nova Holanda in Lacerda's government – some inhabitants worked in building that infrastructure, so they knew how to do it to build it connected with Parque Maré. (Vaz, 1994)

The embankments were also done collectively, in a “mutirão” system, street after street. They were first done with coal, and later the inhabitants were informally settled with the truck drivers for them to throw material like construction debris and earth from demolition of hills. The water was coming from far away, stored inside barrels. These barrels were put inside tires, and rolled all the way to the favela. The electricity was illegally taken from the public system. (Vaz, 1994)

The 70's and 80's

On 1975 the removal moment ends, and 52 favelas stay in middle and high class neighborhoods. Even though there were great removals during almost a decade, the number of residents in favelas didn't change – people would sometimes sell their new houses and go back to favelas. After 75 there was once again a clientelist period, the same politics lived in the populist governments at Vargas period, with small favors done in exchange of votes, within a authoritarian context (Brazil was still living in a dictatorship period). The political disarticulation of the residents led to a relationship among them and the public authorities based on lack of trust and on a distant perspective, and this supported the clientelist interests of the governments. (Burgos, 2006) In Maré, it was a moment of continuation of the work being done, structuring more the areas, but it was only in the end of the 70's, beginning of the 80's that the whole area saw once again a moment of great transformations. There was a lot to be done in these territories: in 1980 only 1% of the favelas had a completed sewage system; 6% had a complete system of water provision and only 17% had a satisfactory garbage collection. From 83 to 85 the municipal company of water (CEDAE) builds a program to bring water and sewage systems to 60 favelas, the garbage company buys micro trucks to access some areas in communities and there is also a program of public lightning in 85. If in one hand these initiatives represent a different approach to these territories, on the other hand its representation and identification as the area of poverty, immorality and crime¹⁰⁰ does not help in the overcoming of the stigma of

¹⁰⁰ In the 80's the organized crime groups in favelas grow, particularly the drug dealers. There is a strong relationship between this phenomena of violence and the clientelist moments that disturbed the processes of political organization of the inhabitants of these areas: “The coincidence between the democratic transition and the privatization of the favelas by these parallel powers is particularly dramatic because it establishes a continuity with the tragedy lived during the military regime. The embarrassments that these parallel powers impose to the local political organizations, inclusive with the murderer of many of their leaderships, follow up the terror that was before imposed by the state.” (Burgos, 2006) p.44.

these territories and its segregated condition.

In 1979 the military government had their last program executed, focused on urbanization. It was called PROMORAR and the first project of PROMORAR was Projeto Rio. The whole program started in 1979 and was financed by BNH (National Housing Bank), the same bank that financed the construction of the new housing units in the removals time of Lacerda's government in the 60's. In the debate of PROMORAR the discussion is not, for the first time, between urbanizing or removing the favelas but how to integrate these areas in the city, and it means a great advance from the previous programs and projects. Projeto Rio was to be implemented in areas where people were living in precarious conditions, in watered areas, and since it was the case for many houses in Maré, there was a seen risk of eviction and its main objectives of Projeto Rio is to improve basic infrastructure (sewage mainly), to eliminate the existing stilt houses and to give property entitlements to the residents.

To recover flooded stripes inhabited, pretending, with the valorization of the areas that are then conquered, to recover the investments done (...) the Projeto Rio would be developed in areas close to the international airport, reaching six favelas in Maré: Parque União, Rubens Vaz, Nova Holanda, Baixa do Sapateiro, Timbau and Maré. (Burgos, 2006)

The residents of Maré, when first told about the program, were afraid of being evicted from the area. The residents associations mobilized and actually Projeto Rio ended in having positive effects in the whole territory, with no attempts to remove the population from the area. People living in stilt houses were moved to new popular houses built in Maré, in other vacant areas. The inhabitants of Timbau and of some other areas, had their property entitlements rights given (1057 in whole Maré) in this period and the territory actually became more consolidated with the construction of new areas, with the government planning for the residents to stay in the area, together with people that came evicted from risk prone areas of other favelas of the city. (Burgos, 2006)

In 1979 Baixa do Sapateiro had around 20 000 inhabitants, and still had a great number of stilt houses, where people lived in very bad conditions. Some houses were built on top of an open air sewage, and when the tide increased, people had black sewage water in their houses. These houses were taken during the implementation of Projeto Rio and the population moved to the new housing units (1534 units) built in 1982 in Vila do João. The project was extremely important for the community of Baixa do Sapateiro, that became free from the stilt houses challenge and its property rights given, and since that at that time almost all basic infrastructure was built in the community, and the houses were already made out of bricks, it was turning out to be a even more consolidated and structured area.

The government also paved some of the streets of Parque Maré and the area had many improvements, with official water provision systems and electricity.

Even though it was a period of greater consolidation¹⁰¹ that extension of the occupations, Timbau's occupation kept on growing and in the 80's, in the area where previously was the beach of Inhaúma, were built low income apartment houses.

The existence of basic infrastructure has strong relation with the early creation of a residents association and its historical active projects and also from the fact that by being a hill, people didn't have to care about creating their own land, and spent greater investments in improving their infrastructures.

The 90's

Projeto Rio was just finished in all the favelas in 1992, after strong protests from residents associations, asking for its ending. For instance, in Baixa do Sapateiro there were promised sewage infrastructure and urban improvements that were not built or finished in the early 80's. In 1985 these construction re-started and stop once again, but only in 1990 almost all sewage and water provision were completed.

¹⁰¹ In 1987 for example, 92% of the houses in Timbau were brick houses. (Vaz, 1994)

The Linha Vermelha (Red Line) was built in 1992 and in that time the population of Maré decided with the planners what to do with the area between the communities and the highway. There was built Vila Olímpica, a big area dedicated to sports and leisure activities, managed by the municipality until today. It is a semi-closed space, where people can have access, but it is a fenced area.

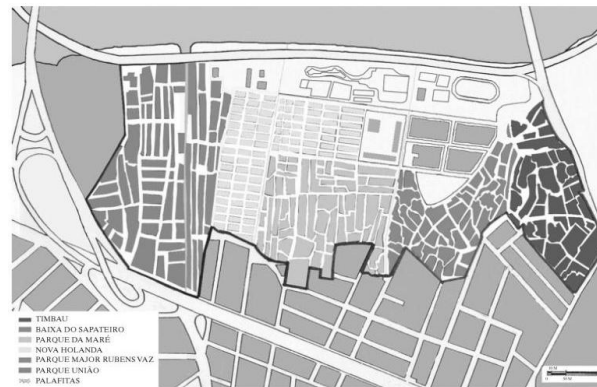

Figure 3. Part of the area of Maré in the 90's, after Projeto Rio (source: Projeto Rio, design by Leandro C. Rodrigues, taken from Vaz & Jacques (2004)).

Since then

All these irregular places are today consolidated and dense urban areas. They have great provision of economic activities and social connections between the residents. It is very usual in these areas, as well as in the greatest part of Maré, that people keep on growing their houses as family grows, or improve their living conditions as their economic life evolves. There are no more wood or stilt houses in Maré, with the exception of a small area, commonly known as Favela Mac Laren, where people do live in extremely poor conditions, without basic infrastructure provided. However this favela dates from round 10 years ago, and being located between Morro do Timbau and Vila do Pinheiro, it does not belong directly to any of these residents association areas of intervention. It is a case of exception within Maré, where today more than 130 000 people live with, at least, basic housing and urban conditions.

Morro do Timbau, together with Parque União, are the areas in Maré with higher housing prices, known in Maré, between their residents as the “south zone” of Maré.¹⁰²

Parque Maré is a completely consolidated area, with all the houses built in bricks and with no urgent problems related to basic infrastructure. Rua Teixeira Ribeiro, in Parque Maré, is one of the most known streets in all Maré, with a great economical dynamic and one of the most famous street markets of the whole favela. In the project for a new BRT (Bus Rapid Transit) line passing in Avenida Brasil (called Transbrasil) it is included a BRT transit stop nearby Parque Maré, which will improve the access and direct connection between this area and the rest of the city.

The places with regular guidelines

Nova Holanda, Rubenz Vaz, Parque União, Conjunto Pinheiros, Vila do Pinheiro, Salsa e

¹⁰² The South Zone refers directly to the identity of a richest area. In Rio, the south zone of the city is the wealthiest part of the whole urban area, where the neighborhoods of Copacabana, Ipanema, or Leblon (to name few) are located. To live in the “South Zone” is then directly related with wealth. Timbau and Parque União are in Maré the “South Zone” areas.

Merengue, Vila do João, Bento Ribeiro Dantas, Nova Maré, Conjunto Esperança

The places in Maré with regular layouts have two main different backgrounds. There are the cases where the regularity was determined locally, mainly with the intervention of Mr. Margarino Torres in Maré. These places date from earlier moments and are a local attempt to organize and structure the areas based on predetermined physical strategies. These places are not as regular and orthogonal as the other ones, where the public government implemented projects of low income housing for the residents. In both cases the main common fact is that it is not about spontaneous occupation, but rather planned and organized processes of urban development. Both these areas, because of its planning processes and final regularity are the closest ones to the planning logics of the ordered city, and can easily be understood as being anything but informal areas.

1950's

Parque União is the most consolidated area of Maré, with a very well defined urban structure and a high housing prices. It has large streets, some well defined sidewalks and very few alleys. It started to be occupied in the middle of the 50's, on a spread occupation in the parts that are nearest to the Avenida Brasil. Threatened of removal by the government, in the end of the decade Margarino Torres, a communist lawyer, is called to support started planning and coordinating the occupation of the area, managing the land distribution and selecting the residents to come to the area (for example, only people with permanent work could settle in). His plan of organized occupation was followed until 1969.

The portions of land were sold¹⁰³ to the new residents that needed to follow the rules of the space – it was forbidden to have illegal activities within the area, like prostitution, if someone would build a house without permission he would set the fire on the house and each inhabitant could only owe one piece of land. (Vaz, 1994) Margarino controlled morally and judicially the occupation, and prevented the residents from potential actions from the police, acting judicially towards the police initiatives: the policemen needed to be identified in order to get into the area. On the other hand, Margarino started to be accused of charging for fees and not improving the area, and his story in Maré ends with an episode of a murdering of a local resident.¹⁰⁴ This second phase of occupation happened in a fringe of land close to the water channel (bordering Rubens Vaz) that was left that was an embankment done by a private company that then left it without occupying.

The planning of the area took into consideration issues of housing and mobility, with plots with an area around 70 sq.mt and a well defined layout of streets. The occupation of the whole

¹⁰³ “When rumors of a SERFHA-led expulsion began to circulate, one of the residents decided to call on Magarinos Torres, based on his reputation as a powerful friend of threatened favelas. Magarinos Torres accepted the charge, setting up a neighborhood organization, re-naming the area the “Bairro Operário Desembargador Magarinos Torres (after his father), and collecting money that he said would cover court fees and neighborhood improvements.” (Fischer, 2013)

¹⁰⁴ “In Alexandrino’s retelling he had initially paid and collected the fees without question, trusting that Magarinos Torres was using the funds to defend local land claims and “urbanize” a favela initially entirely destitute of water, drainage, electricity, schools, or roads. As the months went by, however, Magarinos Torres raised the fees, charging as much as 40,000 cruzeiros as an entry fee, in addition to a monthly charge of CR\$1000. The promised improvements never materialized. Magarinos began to demand that new residents be registered voters, and that they go along with his “political activities,” imposing increasingly violent penalties – expulsions, shack burnings, beatings – on those who violated his terms. When João Alexandrino began to question those activities – leaving the local association, seeking a personal audience with Governor Carlos Lacerda to report the “crimes” and circulating a petition against Magarinos Torres that would eventually become the foundation for the police land-grabbing inquiry – Magarinos Torres began a series of steadily escalating threats against Alexandrino and his family, which culminated in his cousin’s assassination.” (Fischer, 2013).

area followed 5 different phases, moving towards north and east, and the development management included the payment of fees from the population that were then applied in urban improvements and to pay the services done by Mr. Margarino. (Vaz, 1994)

Rubens Vaz is the favela with the smallest ground level area within Maré. Located in a small fringe between Nova Holanda and Parque União, started to be occupied in 1951 on a sand area that was left from the canalization of the water channel of portuária. João Araújo, that was an inhabitant, started to organize the area and define the streets layout. Being occupied in the 50's, all the houses were first made out of leftovers of wood, since it was strictly forbidden to build houses with bricks in favelas on that moment of strong removal policies. It was then a place where people lived in very hard conditions, living in a very flood prone area and without allowance to build with more permanent materials. The area hadn't basic infrastructure, and in 1954 the population itself found a way of divert water from the pipes that passed under Avenida Brasil and have a water source within the community. Before that, the residents of other communities needed to bring water from Bom Sucesso, in the other side of Av. Brasil, crossing the high traffic carrying the drinking water (many people died hit by cars in this period). Afterwards, the whole area was able to have their own water provision individually at each home. (Vaz, 1994)

The embankments were done by the residents, with chalk (thrown out in the area by the state gas company) and construction debris that truck drivers would leave in the area in exchange of payments. The residents build their structured land and the occupation kept on developing and growing. The authorities paid attention to it and decided to act in order to stop the development of the area and this is when Margarino Torres steps in and fights for the permanence of the population in that place. He becomes a strong community leader and this part of Maré, first named as “areal” (in connection with the sand that existed there), is called “Margarino Torres” until 1965. (Vaz, 1994)

Its morphology is both determined by the layout defined when it was occupied, the area that was available with sand from the channel works and from the channel itself: Rubens Vaz is located between the “valão” (the current name for the channel, since it became a open air sewage and garbage deposit) and Nova Holanda.

1960's

A refavela

Revela o salto

Que o preto pobre tenta dar

Quando se arranca

Do seu barraco

Prum bloco do BNH

Refavela – Gilberto Gil. 1977

In 1960 the federal district moves from Rio de Janeiro to the new built Brasília. It is a very important time, when Rio goes from the main city of the country to being the State of Guanabara. Carlos Lacerda, a famous journalist, is the first governor of the new state and him, that was in the past a communist, starts one of the most hard decades for the favelas of Rio. The 60's is the decade of great urban and social traumas, with great removals and tragedies, and the institutionalization and re-enforcement of the favela seen as a problem and a issue to be controlled and, if possible, eliminated. It is known as the period of the big removals, both from the favelas and from the proletarian parks that were built in the 40's. It was created the National Housing Bank (BNH) that supported the construction of new settlements with popular housing far away from the south zone and the city centre of Rio, to where the population of favelas (mainly the ones located in areas of high real estate interest) were sent. The construction of Cidade de Deus (City of God) and Vila Kennedy date from this period. It was also a moment of

great investments and financial support in Brazil from the U.S. (through USAID) (Burgos, 2006).

For the re-location of the ones living in the favelas that were removed it was created low income permanent housing projects (like City of God or Vila Kennedy), far away from the city centre and the South Zone, in suburban areas, and also temporary housing projects. These ones were designated to the poorest ones within the poor, considered to be un-civilized, immoral and dirty. The idea was that these people would stay at the temporary housing projects for some time, get educated with moral values and hygienic principles in a extremely high controlled environment and afterwards, they would be sent to more permanent housing, when they would be ready to live within a more civilized world. This segregationist approach, together with the great removals, was responsible for the construction of a great trauma among the urban poor, detached from their territories and divided, separated from their closer ones and from their urban contexts. Many of these people, living in favelas in the south zone, worked in the same area but after the removals they faced difficulties on finding work opportunities and building their new social context.

The foundation Leão XIII, created in the 40's by the church is revitalized, becoming part of the municipal secretary of social services in 1962. This foundation will be one of the main responsible for the management of the removal processes and the control of the new settlements, the administration of the temporary housing centers, registration of people and definition of the centre of destiny for them. (Burgos, 2006)

This is a political moment towards the favelas that somehow reinforces and evolves from the politics that were taken 20 years earlier, with the Code of Constructions from 37 (Código de Obras) and the building of the proletarian parks, when favelas are understood as being undesired territories and its population being represented as the responsible for urban problems. Once again, the same story repeating, in an attempt to organize and control the urban land, segregating the poor areas far away from the wealthiest and high real estate valued places.

“With the increase in planned slum shifting, and the rising proportions of “relocated” people in new projects, these new projects are sometimes starting off today with the sullenness and discouragement typical of old projects or of old perpetual unplanned slums – as if they had already, in their youth, been subjected to the vicissitudes of many disruptions and disintegrations. This is probably because so many of their residents have already lived with such experiences, and of course take them along as emotional baggage.” (Jacobs, 1961)p. 278.

The story, once again, influences and reflects directly on the urban morphology of Maré: in 1962 the first inhabitants of Nova Holanda arrive in the area. Nova Holanda was one of the 3 temporary housing centers built with financial support from the USAID that created COHAB-GB. On these 3 centers and the 3 new permanent areas built in the city were relocated people from the 12 favelas that were removed. This means that, in the case of Nova Holanda, people from the old favela of Esqueleto, Praia do Pinto, Faria-Timbó and Querosene were settled together in the centre. These people had no relationships among them, and it ended up in being an area with inner segregations. When it was occupied its construction wasn't completely finished, with some houses to be concluded. (Redes de Desenvolvimento da Maré, 2010)

Morphologically, it is a very interesting area of Maré. Nova Holanda was built upon a new huge embankment done between Rubens Vaz and Parque Maré, that in that period were already occupied. It had provision of basic infrastructure and the houses were built with wood, brick or both. There were two different housing layouts: single and duplex houses, and each house was for a single family.

The construction was done in two phases (first on the northern area until Rua Sargento Silva Nunes, and then the southern area, until the limits of Parque Maré). It has a completely orthogonal layout, with very well defined structure, without alleys or cul-de-sac, in a totally flat and regular area. (Vaz, 1994)

It was not an occupied area, it was not illegal occupation, it was not informal or spontaneous, it was not abandoned or chosen by the population, it was not supposed to last for a long time and even though, it became a favela. The case of Nova Holanda should be itself a paradigm to

understand what is it about processes of “favelization”, and to which extent can the public authorities be part of that process, but that is not the objective of this paper. However, considering the urban strategy of this area and its occupation process one may address what possibly creates the perception and identification of informality that has nothing to deal with urban form itself.

Because it was planned to be a temporary housing centre, the houses were built with fragile materials and the basic infrastructure was not planned to support long term usages. Also, the population was completely forbidden of making any improvements in their houses or in the area, in risk of transforming this houses into more permanent units. Also, coming from different areas of the city, there were conflicts installed among the residents, which fumbled possible social organizations (the residents association was only formed in the 80's) and mobilization for urban improvements.

It ended up in being a permanent settlement, and the population did not leave the centre to be relocated in any other popular housing units, and as time passed, the houses started to get destroyed – and not improved – and the basic infrastructural services were not attending properly the growing population without any maintenance procedures. Since there was no consideration related to time resistance and adaptation, the area started to have some of the worst living conditions of whole Maré, becoming a place of shanties. (Vaz, 1994)

So, one may say that the political understanding of the favela as places to avoid, the cleaning of the city, marked the whole history of Nova Holanda. Its morphology and further processes of “favelization” are deeply connected – and dependant – on the strategies for social control: the fact that it was planned to be a temporary housing center, and that it was controlled to stay like that for many years, together with the difficulties of self organization and mobilization has its origins also in the planned initiative and the authoritarianism of Leão XIII, representing of the oppressor government.

If Nova Holanda is a great testimonial of the politics of favela removals that happened in the 60's, it is curious to understand that in this period some of the areas of Maré had their biggest improvements. The population kept on growing in the whole favela, and in some places the residents themselves improved their urban infrastructures, embanked new areas, and kept on occupying land. Margarino Torres was a very important character in this period, since he supported the development of two favelas (Rubens Vaz and Parque União), organizing it and giving a judicial support to the residents of these areas. It is a fact that both favelas had great improvements in the 60's, becoming structured places densely occupied. Once the area of Maré was at that time still a non-valued area for the real-estate market – the city was still having big investments in the centre and south zone, and moving towards west (Cidade de Deus and Rio das Pedras were built so that the people moved to there would be probably working on the building of Barra da Tijuca, the new area of the city in great development), and also with Avenida Brasil having its industries working all along it and being already the most congested way of Rio, Maré was then a very strategic place for workers to locate and at the same time it did not threatened the urban logics of development of Rio. There are stories of corruption within Maré's development, with the police and Fundação Leão XIII selling houses in Nova Holanda, and it may have happened in other areas of Maré. No matter what, it is important to understand that in Maré there were no stories of removal, but stories of population increase during the decade. In fact, Maré kept on growing and increasing its population until today, and that is also why it is such a rich and valuable case-study to understand the evolution and patterns of organization of favelas in different contexts and historical periods.

In 1961, the east area of Rubens Vaz was embanked, at the same time as the government was doing the landfill in Nova Holanda. The area had urban improvements on basic infrastructural services that were either given officially by the government (electricity and better water pipes) or constructed by the population (the sewage system is then directly sent to the water channel). In the same year, Margarino Margarino Torres leaves the management of Parque União with its residents associations elected (in 1961) and they keeps on following almost the same guidelines, continuing the development of that part of Maré. In 1965 the residents association of Rubens

Vaz is registered, and has a politics of controlling and organizing the allowance and distribution of residents in the area, selecting whom could live there and charging fees to the residents. (Vaz, 1994)

In Parque União, the houses were made out of wood, since it was forbidden to build in bricks in favelas, but the population started to build brick walls behind the wood, and once the house was finished, the wood panels could be removed. It was also the time of the 5th phase of occupation of Parque União and if in the first 4 phases the inhabitants had their property entitlements immediately, in the last phase it took more than 20 years to have the entitlements. In this period, the inhabitants needed to embank some areas, even though there was a preexistent embankment done, it was not enough to settle everyone. It was also the period of greater urban improvements: first, the population (similarly to what they did in Rubens Vaz) found a way of connecting the water provision infrastructure with the pipe passing under Avenida Brasil, but once it is found by the municipality it is determined to be destroyed. However, the residents mobilize and the public authorities decide to make an official connection replacing the informal one. However, ironically, the official connection has pressure problems and the populations finds it better to re-make the informal one they had before, increasing and improving it. Also in 1963 is installed the first electricity network, Also in 61 some streets have already sewage pipes built, conducting the sewage to the channel that divided Pq. Uniao with Rubens Vaz, to the bay, and to other channel that passes under R. São Sebastião. In 1962 the streets are paved for the first time. (Vaz, 1994)

In 1964, when the municipality decides to build a new freeway passing side by side with Avenida Brasil, a new embankment is done to re-locate the inhabitants living on the fringe close to the avenue. However, this freeway is not built (it will be build only in 1992 and in a completely different layout) and the population start occupying the landfill left by the municipality. This was also the phase when all the embankments were done in the full area (and after the houses were built, usually another embankment was done to reinforce the streets) that today is Parque União, completing the construction of its own land by its population and as soon as land was conquered to the water, it was immediately occupied by new residents coming to Maré. This last occupations were more irregular than the ones done while Mr. Margarino Torres was managing the area, and it is very clearly to see two main different street layouts in Parque União. The streets start having smaller widths and stop following the more orthogonal matrix done while at Margarino's period. (Vaz, 1994)

The 70's

“The environment is, with no doubt unfavorable. (...) It is hard, if not extremely impossible, to recover men, women and children in an environment like the one in favelas. Because oh what we decided for the arduous, but fruitful, work of eradication” (CHISAM, 1971: 31).
cited in (Brum, 2012)

With its territory completely occupied, and with almost one decade of existence, Nova Holanda becomes overpopulate and its basic infrastructure systems collapse. People went back to carry the water from far away, as in the old times in other favelas of Maré, and the area is already becoming unable to support the permanent and growing occupation without any urban improvement. (Vaz, 1994)

The social conflicts within the center kept on growing with clear segregation and separation accordingly to the favelas where the inhabitants were coming from (remembering the fire on Praia do Pinto was in 69, so this population was relocated to Maré in this period and facing issues of integration and relation with the other residents). This processes designed new identifications and conceptualizations within the area, subdividing the territory and breaking its perception as a unit: the duplex area, where people from Praia do Pinto were located, was known as the Vietnam, because it was considered a very dangerous area. (Vaz, 1994) Morphologically these differences were also easy to understand, since the duplex units built were the place for the ones coming from Praia do Pinto, having then a physical differentiation

from the other ones already living in Nova Holanda.

This segregation was supported by the foundation Leão XIII, probably within a strategy of segregation in order to avoid mobilization and organization among the residents that could put in risk the authority of the institution and the urban project that was implemented there.

In the government of Moreira Franco, the streets of Rubens Vaz are paved, the streets of Parque União are re-paved and the basic infrastructural systems are improved. The pavements are done on a basis of a “street commission”, where people would collect money and take decisions about the material to pave their streets. It was a self organized process. (Vaz, 1994)

The 80's

In 1982 Brizola is elected in Rio with a political agenda strongly focused on social priorities, focused on improving favelas and its infrastructure. He represents in that period the alternative way against the authoritarian clientelism that for so many moments controlled the relationships between politicians and the city, mainly the favelas.

It is a very different moment that is being lived now, with a different approach towards the favela, but since the residents were so used to be threatened of removal, they were at first afraid of being taken from Maré once that the stilt houses would be demolished. They mobilized and somehow opened the dialogue with the authorities and in fact, everyone that was previously living in stilts were re-located inside Maré to one of the different projects that Projeto Rio built there.

Some of these projects were made out of single houses, while others were apartment blocks, but all within the limits of what is Maré today. This is a moment where all development in Maré is done on a regular morphological perspective, and the experiences had already shown that if the projects are not flexible and able to be adapted accordingly to the residents needs they don't succeed as expected. There is no need to make a deeper analysis of the morphological definitions, since they are, at this point, mainly resultant from the housing layout decisions and issues of design priorities. It would be necessary to get into architectural and urban design paradigms of the moments, and that is not the aim of this work. All the projects have, however, a very strong regular plan, with modular repetitions, either in apartment blocks or when single houses are built. The basic layout and structure remains until today, with individual adaptations in houses. However, one may say that when houses are built individually they are more able to be adapted and give better flexibility to the residents to evolve or modify their layouts according to their own needs. Apartment blocks may give a more rigid morphology, and unable some intuitive transformations of its residents. In both cases, there is a strong modernist perspective upon the plans and their distribution, based on functionalistic logics and normative, orthogonal form.

The most important is to reinforce that this was a moment of structuring and development of the whole area, with a greater definition of its favelas, stabilizing more the occupation and morphological distribution. Once you have the public authorities and the government building and planning in Maré for permanent assets, it means the achievement of the urban recognition of this territory's part of public strategies for urban development of the whole city. However, this is focused mainly in housing issues at this time, with the communities lacking public services until today. For this research it is extremely important to see how urban morphology radically changes when a new logic is placed. This is fundamental to understand the diversity that exists within Maré, and to acknowledge that in fact this is not the first moment that public policies influence Maré's development – it has always happened, the main difference is that now this action had immediate and direct impacts on the urban form.

In 1982 the sewage system of Rubens Vaz is improved, built by the government. During projeto Rio, the last embankment of the area is done. (Vaz, 1994)

The first election for residents association in Nova Holanda happened only in 1984, and was planned since 79, with the threat of Projeto Rio to remove the favelas in Maré. Women and young people are the main responsible for the achievement of a collective thinking, and an

organization of the community in order to allow the existence of the residents association in an area that was initially full of conflicts. The elections were won against the Foundation Leão XIII, through a remarkable community empowering process. (Redes de Desenvolvimento da Maré, 2010)

In Projeto Rio, the people living on stilt houses were re-located to new housing units within Maré and some of the areas where the stilt houses were located, were then embanked by the project. It is in this context that Conjunto Esperança, Vila do João, Conjunto Pinheiro and Vila do Pinheiro are built:

Conjunto Esperança is the southern area of Maré. It is a completely planned area, with blocks of apartments. It does not have direct access via Avenida Brasil, because it is located behind the main building of the FIOCRUZ foundation (a health foundation). When it was built, there were no business or commercial activities proposed for the area, and the residents did not accept the project so well in the beginning because they felt the lack of services and urban dynamics there. However, with time the area consolidated, adapted and the population became more familiar with their new context. (Redes da Maré; Observatório de Favelas, 2012)

Vila do João is located North from Conjunto Esperança and faces Avenida Brasil. It was built in the same context and also for the relocation of people in stilt houses in Maré, but it has a single housing layout proposal. The residents of Vila do João were given property entitlements in the moment of relocation, and because of that it is the area of Maré where almost everyone has their property rights ensured. It is interesting to understand that Vila do João area was an airport and a flight training center from the 30's to the 70's, that was demolished because it started to be seen as an unsafe place to do trainings – there was an accident between one plane that was training with a commercial flight coming from the international airport. (O GLOBO, 2014) It was then an area already defined, completely flat and with a very specific previous occupation. There are no infrastructural buildings left from that period.

In Conjunto Pinheiro, located east from Vila do João, were built the last apartment blocks (34 units) of Projecto Rio, in 1989. Without maintenance, in 1999, the residents protested for urban improvements of the area, that were then implemented by the state housing company (CEHAB). (Redes da Maré; Observatório de Favelas, 2012)

Vila do Pinheiro was built in the context of the second phase of Projecto Rio. It is an area of small houses built upon embankments done in order to connect the Island of Pinheiros with land. This island had an elevated area, that became the first (and only one) ecological park in a favela in Rio – Parque ecológico pinheiros.

Projecto Rio left Maré in 1985, and was publicly announced that all the construction and improvements were done in Maré, but after popular mobilization the project returns to finish works that were still undone.

The 90's

In 1990 around 90% of the infrastructure was done in Maré, and the houses of Nova Holanda were already connected to the electricity network. Rubens Vaz had 98% of the houses with electricity, 86,04% connected to the sewage system, 96,63% with water provision, and 88,55% of houses were made out of brick.

From that moment, there were attempts to plan collectively the improvement and construction of houses in Nova Holanda. The creation of COOPMANH by the residents association, had the purpose to collectively manage building materials in order to give access to everyone to improve their houses. It didn't work out as it was planned and then it was created a factory of concrete bricks with support from the government, that sold those bricks 20% cheaper (in 1990). In 1992 were reconstructed 46 houses from the duplex area. Today, there are no more wood houses in Nova Holanda. Nova Holanda has one of the most impressive stories of self organization after 22 years of authoritarianism and segregation among residents, and achieved amazing results in urban development and consolidation. (Redes de Desenvolvimento da Maré, 2010).

The streets morphology of Rubens Vaz changed among the years. It was first organized as two main streets connected through alleys on a very longitudinal distribution but as time passed, these alleys were closed by the populations, occupied by houses. There is also the argument that the alleys were closed because they were crime prone areas. (Redes da Maré; Observatório de Favelas, 2012)

In the 90's there were also other areas being built with initiatives from the public government.

In 1990 Bento Ribeiro Dantas was built to locate people that came from other favelas and areas in Rio considered to be risk prone areas. Bento Ribeiro Dantas is located where was in the past the Inhaúma port, an important infrastructure for the city before the train system was installed. In 1995 the community had its residents association. (Redes da Maré; Observatório de Favelas, 2012)

In 1991 the red line is built and it brings transformations for the area. A big embankment is done in Conjunto Esperança in order to allow to build the freeway, on the area that before bordered Maré with the water in the south. Contemporary to the red line, the municipality built Vila Olímpica, a recreational area focused on sports activities located on a big area, on the east side of Maré. Also after the construction of the red line, it was built a wall all the way that borders the freeway with Maré, justified by the municipality as a way of reducing noise from the cars in the community. There are some different positions about that, considering that it was a strategy to cover Maré from the view of tourists that come all the way from the airport to the city centre through the red line.
